Nearly four years later he emphasised his dissent from what he considered to be the current geological opinions of the day by repeating the same argument in a more pointedly antagonistic form in a paper of only a few sentences, entitled, "The Doctrine of Uniformity in Geology briefly refuted" (*Proc. Roy. Soc. Edin.*, vol. v. p. 512, December 18, 1865).

Again, after a further lapse of about two years, when, as President of the Geological Society of Glasgow, it became his duty to give an address, he returned to the same topic and arraigned more boldly and explicitly than ever the geology of the time. He then declared that "a great reform in geological speculation seems now to have become necessary," and he went so far as to affirm that "it is quite certain that a great mistake has been made—that British popular geology at the present time is in direct opposition to the principles of natural philosophy" (*Trans. Geol. Soc. Glasgow*, vol iii., February 1868, pp. 1, 16). In pressing once more the original argument derived from the downward increase of terrestrial temperature, he now reinforced it by two further arguments, the one based on the retardation of the earth's angular velocity by tidal friction, the other on the limitation of the age of the sun.

These three lines of attack remain still those along which the assault from physics is delivered against the strongholds of geology. Lord Kelvin has repeatedly returned to the charge since 1868, his latest contribution to the controversy having been pronounced two years ago.[1] While his physical arguments remain the same, the limits of time which he deduces from them have been successively diminished. The original maximum of 400 millions of years has now been restricted by him to not much more than 20 millions, while Prof. Tait grudgingly allows something less than 10 millions ("Recent Advances in Physical Science," p. 174).

Soon after the appearance of Lord Kelvin's indictment of modern geology in 1868, the defence of the science was taken up by Huxley, who happened at the time to be President of the Geological Society of London. In his own inimitably brilliant way, half seriously, half playfully, this doughty combatant, with evident relish, tossed the physical arguments to and fro in the eyes of his geological brethren, as a barrister may flourish his brief before a sympathetic jury. He was willing to admit that "the rapidity of rotation of the earth *may* be diminishing, that the sun *may* be waxing dim, or that the earth itself *may* be cooling." But he went on to add his suspicion that "most of us are Gallios, 'who care for none of these things,' being of opinion that, true or fictitious, they have made no practical difference to the earth, during the period of which a record is preserved in stratified deposits" (Presidential Address, *Quart. Journ. Geol. Soc.*, 1869).

For the indifference which their advocate thus professed on their behalf most geologists believed that they had ample justification. The limits within which the physicist would circumscribe the earth's history were so vague, yet so vast, that whether the time allowed were 400 millions or 100 millions of years did not seem to them greatly to matter. After all, it was not the time that chiefly interested them, but the grand succession of events which the time had witnessed. That succession had been established on observations so abundant and so precise that it could withstand attack from any quarter, and it had taken as firm and lasting a place among the solid achievements of science as could be claimed for any physical speculations whatsoever. Whether the time required for the transaction of this marvellous earth-history was some millions of years more or some millions of years less did not seem to the geologists to be a question on which their science stood in antagonism with the principles of natural philosophy, but one which the natural philosophers might be left to settle at their own good pleasure.

For myself, I may be permitted here to say that I have never shared this feeling of indifference and unconcern. As far back as the year 1868, only a month after Lord Kelvin's first presentation of his threefold argument in favour of limiting the age of the earth, I gave in my adhesion to the propriety of restricting the geological demands for time. I then showed that even the phenomena of denudation, which, from the time of Hutton downwards, had been most constantly and confidently appealed to in support of the inconceivably vast antiquity of our globe, might be accounted for, at the present rate of action, within such a period as 100 millions of years.[1] To my mind it has always seemed that whatever tends to give more precision to the chronology of the geologist, and helps him to a clearer conception of the antiquity with which he has to deal, ought to be welcomed by him as a valuable assistance in his inquiries. And I feel sure that this view of the matter has now become general among those engaged in geological research. Frank recognition is made of the influence which Lord Kelvin's persistent attacks have had upon our science. Geologists have been led by his criticisms to revise their chronology. They gratefully acknowledge that to him they owe the introduction of important new lines of investigation, which link the solution of the problems of geology with those of physics. They realise how much he has done to dissipate the former vague conceptions as to the duration of geological history, and even when they emphatically dissent from the greatly restricted bounds within which he would now limit that history, and when they declare their inability to perceive that any reform of their speculations in this subject is needful, or that their science has placed herself in opposition to the principles of physics, they none the less pay their sincere homage to one who has thrown over geology, as over so many other departments of natural knowledge, the clear light of a penetrating and original genius.

When Lord Kelvin first developed his strictures on modern geology he expressed his opposition in the most uncompromising language. In the short paper to which reference has already been made he announced, without hesitation or palliation, that he "briefly refuted" the doctrine of Uniformitarianism which had been espoused and illustrated by Lyell and a long list of the ablest geologists of the day. The severity of his judgment of British geology was not more marked than was his unqualified reliance on his own methods and results. This confident assurance of a distinguished physicist, together with a formidable array of mathematical formulæ, produced its effect on some geologists and palæontologists who were not Gallios. Thus, even after Huxley's brilliant defence, Darwin could not conceal the deep impression which Lord Kelvin's arguments had made on his mind. In one letter he wrote that the proposed limitation of geological time was one of his "sorest troubles." In another, he pronounced the physicist himself to be "an odious spectre" (Darwin's "Life and Letters," vol. iii. pp. 115, 146).

The same self-confidence of assertion on the part of some, at least, of the disputants on the physical side has continued all through the controversy. Yet when we examine the three great physical arguments in themselves, we find them to rest on assumptions which, though certified as "probable" or "very sure," are nevertheless admittedly assumptions. The conclusions to which these assumptions lead must depend for their validity on the degree of approximation to the truth in the premisses which are postulated.

Now it is interesting to observe that neither the assumptions nor the conclusions drawn from them have commanded universal assent even among physicists themselves. If they were as self-evident as they have been claimed to be, they should at least receive the loyal support of all those whose function it is to pursue and extend the applications of physics. It will be remembered, however, that thirteen years ago Prof. George Darwin, who has so often shown his inherited sympathy in geological investigation, devoted his presidential address before the Mathematical Section of this Association to a review of the three famous physical arguments respecting the age of the earth. He summed up his judgment of them in the following words: "In considering these three arguments I have adduced some reasons against the validity of the first (tidal friction); and have endeavoured to show that there are elements of uncertainty surrounding the second (secular cooling of the earth); nevertheless they undoubtedly constitute a contribution of the first importance to physical geology. Whilst, then, we may protest against the precision with which Prof. Tait seeks to deduce results from them, we are fully justified in following Sir William Thomson, who says that "the existing state of things on the earth, life on the earth—all geological history showing con-

[1] "The Age of the Earth," being the Annual Address to the Victoria Institute, June 2, 1897. *Phil. Mag.*, January 1899, p. 66.

[1] *Trans. Geol. Soc. Glasgow*, vol. iii. (March 26, 1868), p. 189. Sir W. Thomson acknowledged my adhesion in his reply to Huxley's criticism. *Op. cit.* p. 221.

tinuity of life—must be limited within some such period of past time as 100,000,000 years" (*Rep. Brit. Assoc.*, 1886, p. 517).

More recently Prof. Perry has entered the lists, from the physical side, to challenge the validity of the conclusions so confidently put forward in limitation of the age of the earth. He has boldly impugned each of the three physical arguments. That which is based on tidal retardation, following Mr. Maxwell Close and Prof. Darwin, he dismisses as fallacious. In regard to the argument from the secular cooling of the earth, he contends that it is perfectly allowable to assume a much higher conductivity for the interior of the globe, and that this assumption would vastly increase our estimate of the age of the planet. As to the conclusions drawn from the history of the sun, he maintains that, on the one hand, the sun may have been repeatedly fed by infalling meteorites, and that, on the other, the earth, during former ages, may have had its heat retained by a dense atmospheric envelope. He thinks that "almost anything is possible as to the present internal state of the earth," and he concludes in these words: "To sum up, we can find no published record of any lower maximum age of life on the earth, as calculated by physicists, than 400 millions of years. From the three physical arguments, Lord Kelvin's higher limits are 1000, 400, and 500 million years. I have shown that we have reasons for believing that the age, from all these, may be very considerably under-estimated. It is to be observed that if we exclude everything but the arguments from mere physics, the *probable* age of life on the earth is much less than any of the above estimates; but if the palæontologists have good reasons for demanding much greater times, I see nothing from the physicist's point of view which denies them four times the greatest of these estimates" (NATURE, vol. li. p. 585, April 18, 1895).

This remarkable admission from a recognised authority on the physical side re-echoes and emphasises the warning pronounced by Prof. Darwin in the address already quoted—"at present our knowledge of a definite limit to geological time has so little precision that we should do wrong to summarily reject any theories which appear to demand longer periods of time than those which now appear allowable" (*Rep. Brit. Assoc.*, 1886, p. 518).

This "wrong," which Prof. Darwin so seriously deprecated, has been committed, not once, but again and again in the history of this discussion. Lord Kelvin has never taken any notice of the strong body of evidence adduced by geologists and palæontologists in favour of a much longer antiquity than he is now disposed to allow for the age of the earth. His own three physical arguments have been successively re-stated, with such corrections and modifications as he has found to be necessary, and no doubt further alterations are in store for them. He has cut off slice after slice from the allowance of time which at first he was prepared to grant for the evolution of geological history, his latest pronouncement being that "it was more than twenty and less than forty million years, and probably much nearer twenty than forty."[1] But in none of his papers is there an admission that geology and palæontology, though they have again and again raised their voices in protest, have anything to say in the matter that is worthy of consideration.

It is difficult satisfactorily to carry on a discussion in which your opponent entirely ignores your arguments, while you have given the fullest attention to his. In the present instance, geologists have most carefully listened to all that has been brought forward from the physical side. Impressed by the force of the physical reasoning, they no longer believe that they can make any demands they may please on past time. They have been willing to accept Lord Kelvin's original estimate of 100 millions of years as the period within which the history of life upon the planet must be comprised, while some of them have even sought in various ways to reduce that sum nearer to his lower limit. Yet there is undoubtedly a prevalent misgiving, whether in thus seeking to reconcile their requirements with the demands of the physicist they are not tying themselves down within limits of time which on any theory of evolution would have been insufficient for the development of the animal and vegetable kingdoms.

It is unnecessary to recapitulate before this Section of the British Association, even in briefest outline, the reasoning of geologists and palæontologists which leads them to conclude that the history recorded in the crust of the earth must have required for its transaction a much vaster period of time than that to which the physicists would now restrict it.[1] Let me merely remark that the reasoning is essentially based on observations of the present rate of geological and biological changes upon the earth's surface. It is not, of course, maintained that this rate has never varied in the past. But it is the only rate with which we are familiar, which we can watch and in some degree measure, and which, therefore, we can take as a guide towards the comprehension and interpretation of the past history of our planet.

It may be, and has often been, said that the present scale of geological and biological processes cannot be accepted as a trustworthy measure for the past. Starting from the postulate, which no one will dispute, that the total sum of terrestrial energy was once greater than it is now and has been steadily declining, the physicists have boldly asserted that all kinds of geological action must have been more vigorous and rapid during bygone ages than they are to-day; that volcanoes were more gigantic, earthquakes more frequent and destructive, mountain-upthrows more stupendous, tides and waves more powerful, and commotions of the atmosphere more violent, with more ruinous tempests and heavier rainfall. Assertions of this kind are temptingly plausible and are easily made. But it is not enough that they should be made; they ought to be supported by some kind of evidence to show that they are founded on actual fact and not on mere theoretical possibility. Such evidence, if it existed, could surely be produced. The chronicle of the earth's history, from a very early period down to the present time, has been legibly written within the sedimentary formations of the terrestrial crust. Let the appeal be made to that register. Does it lend any support to the affirmation that the geological processes are now feebler and slower than they used to be? If it does, the physicists, we might suppose, would gladly bring forward its evidence as irrefragable confirmation of the soundness of their contention. But the geologists have found no such confirmation. On the contrary, they have been unable to discover any indication that the rate of geological causation has ever, on the whole, greatly varied during the time which has elapsed since the deposition of the oldest stratified rocks. They do not assert that there has been no variation, that there have been no periods of greater activity, both hypogene and epigene. But they maintain that the demonstration of the existence of such periods has yet to be made. They most confidently affirm that whatever may have happened in the earliest ages, in the whole vast succession of sedimentary strata nothing has yet been detected which necessarily demands that more violent and rapid action which the physicists suppose to have been the order of nature during the past.

So far as the potent effects of prolonged denudation permit us to judge, the latest mountain-upheavals were at least as stupendous as any of older date whereof the basal relics can yet be detected. They seem, indeed, to have been still more gigantic than those. It may be doubted, for example, whether among the vestiges that remain of Mesozoic or Palæozoic mountain-chains any instance can be found so colossal as those of Tertiary times, such as the Alps. No volcanic eruptions of the older geological periods can compare in extent or volume with those of Tertiary and recent date. The plication and dislocation of the terrestrial crust are proportionately as conspicuously displayed among the younger as among the older formations, though the latter, from their greater antiquity, have suffered during a longer time from the renewed disturbances of successive periods.

As regards evidence of greater violence in the surrounding envelopes of atmosphere and ocean, we seek for it in vain among the stratified rocks. Among the very oldest formations of these islands, the Torridon sandstone of North-west Scotland presents us with a picture of long-continued sedimentation, such as may be seen in progress now round the shores of many a mountain-girdled lake. In that venerable deposit, the enclosed pebbles are not mere angular blocks and chips, swept by a sudden flood or destructive tide from off the surface of the land, and huddled together in confused heaps over the floor of the sea. They have been rounded and polished by the quiet operation of running water, as stones are rounded and polished

[1] "The Age of the Earth," Presidential Address to the Victoria Institute for 1897, p. 10; also in *Phil. Mag.*, January 1899.

[1] The geological arguments are briefly given in my Presidential Address to the British Association at the Edinburgh Meeting of 1892. The biological arguments were well stated, and in some detail, by Prof. Poulton, in his Address to the Zoological Section of the Association at the Liverpool Meeting of 1896.

now in the channels of brooks or on the shores of lake and sea. They have been laid gently down above each other, layer over layer, with fine sand sifted in between them, and this deposition has taken place along shores which, though the waters that washed them have long since disappeared, can still be followed for mile after mile across the mountains and glens of the North-west Highlands. So tranquil were these waters that their gentle currents and oscillations sufficed to ripple the sandy floor, to arrange the sediment in laminæ of current-bedding, and to separate the grains of sand according to their relative densities. We may even now trace the results of these operations in thin darker layers and streaks of magnetic iron, zircon, and other heavy minerals, which have been sorted out from the lighter quartz-grains, as layers of iron-sand may be seen sifted together by the tide along the upper margins of many of our sandy beaches at the present day.

In the same ancient formation there occur also various intercalations of fine muddy sediment, so regular in their thin alternations, and so like those of younger formations, that we cannot but hope and expect that they may eventually yield remains of organisms which, if found, would be the earliest traces of life in Europe.

It is thus abundantly manifest that even in the most ancient of the sedimentary registers of the earth's history, not only is there no evidence of colossal floods, tides and denudation, but there is incontrovertible proof of continuous orderly deposition, such as may be witnessed to-day in any quarter of the globe. The same tale, with endless additional details, is told all through the stratified formations down to those which are in the course of accumulation at the present day.

Not less important than the stratigraphical is the palæontological evidence in favour of the general quietude of the geological processes in the past. The conclusions drawn from the nature and arrangement of the sediments are corroborated and much extended by the structure and manner of entombment of the enclosed organic remains. From the time of the very earliest fossiliferous formations there is nothing to show that either plants or animals have had to contend with physical conditions of environment different, on the whole, from those in which their successors now live. The oldest trees, so far as regards their outer form and internal structure, betoken an atmosphere neither more tempestuous nor obviously more impure than that of to-day. The earliest corals, sponges, crustaceans, molluscs, and arachnids were not more stoutly constructed than those of later times, and are found grouped together among the rocks as they lived and died, with no apparent indication that any violent commotion of the elements tried their strength when living, or swept away their remains when dead.

But, undoubtedly, most impressive of all the palæontological data is the testimony borne by the grand succession of organic remains among the stratified rocks as to the vast duration of time required for their evolution. Prof. Poulton has treated this branch of the subject with great fulness and ability. We do not know the present average rates of organic variation, but all the available evidence goes to indicate their extreme slowness. They may conceivably have been more rapid in the past, or they may have been liable to fluctuations according to vicissitudes of environment.[1] But those who assert that the rate of biological evolution ever differed materially from what it may now be inferred to be, ought surely to bring forward something more than mere assertion in their support. In the meantime, the most philosophical course is undoubtedly followed by those biologists who in this matter rest their belief on their own experience among recent and fossil organisms.

So cogent do these geological and palæontological arguments appear, to those at least who have taken the trouble to master them, that they are worthy of being employed, not in defence merely, but in attack. It seems to me that they may be used with effect in assailing the stronghold of speculation and assumption in which our physical friends have ensconced themselves and from which, with their feet, as they believe, planted well within the interior of the globe and their heads in the heart of the sun, they view with complete unconcern the efforts made by those who endeavour to gather the truth from the surface and crust of the earth. That portion of the records of terrestrial history which lies open to our investigation has been diligently studied in all parts of the world. A vast body of facts has been gathered together from this extended and combined research. The chronicle registered in the earth's crust, though not complete, is legible and consistent. From the latest to the earliest of its chapters the story is capable of clear and harmonious interpretation by a comparison of its pages with the present condition of things. We know infinitely more of the history of this earth than we do of the history of the sun. Are we then to be told that this knowledge, so patiently accumulated from innumerable observations and so laboriously coordinated and classified, is to be held of none account in comparison with the conclusions of physical science in regard to the history of the central luminary of our system? These conclusions are founded on assumptions which may or may not correspond with the truth. They have already undergone revision, and they may be still further modified as our slender knowledge of the sun, and of the details of its history, is increased by future investigation. In the meantime, we decline to accept them as a final pronouncement of science on the subject. We place over against them the evidence of geology and palæontology, and affirm that unless the deductions we draw from that evidence can be disproved, we are entitled to maintain them as entirely borne out by the testimony of the rocks.

Until, therefore, it can be shown that geologists and palæontologists have misinterpreted their records, they are surely well within their logical rights in claiming as much time for the history of this earth as the vast body of evidence accumulated by them demands. So far as I have been able to form an opinion, one hundred millions of years would suffice for that portion of the history which is registered in the stratified rocks of the crust. But if the palæontologists find such a period too narrow for their requirements, I can see no reason on the geological side why they should not be at liberty to enlarge it as far as they may find to be needful for the evolution of organised existence on the globe. As I have already remarked, it is not the length of time which interests us so much as the determination of the relative chronology of the events which were transacted within that time. As to the general succession of these events, there can be no dispute. We have traced its stages from the bottom of the oldest rocks up to the surface of the present continents and the floor of the present seas. We know that these stages have followed each other in orderly advance, and that geological time, whatever limits may be assigned to it, has sufficed for the passage of the long stately procession.

We may, therefore, well leave the dispute about the age of the earth to the decision of the future. In so doing, however, I should be glad if we could carry away from it something of greater service to science than the consciousness of having striven our best in a barren controversy, wherein concession has all to be on one side and the selection of arguments entirely on the other. During these years of prolonged debate I have often been painfully conscious that in this subject, as in so many others throughout the geological domain, the want of accurate numerical data is a serious hindrance to the progress of our science. Heartily do I acknowledge that much has been done in the way of measurements and experiments for the purpose of providing a foundation for estimates and deductions. But infinitely more remains to be accomplished. The field of investigation is almost boundless, for there is hardly a department of geological dynamics over which it does not extend. The range of experimental geology must be widely enlarged, until every process susceptible of illustration or measurement by artificial means has been investigated. Field-observation needs to be supplemented where possible by instrumental determinations, so as to be made more precise and accurate, and more capable of furnishing trustworthy numerical statistics for practical as well as theoretical deductions.

The subject is too vast for adequate treatment here. But let me illustrate my meaning by selecting a few instances where the adoption of these more rigid methods of inquiry might powerfully assist us in dealing with the rates of geological processes and the value of geological time. Take, for example, the wide range of lines of investigation embraced under the head of Denudation. So voluminous a series of observations has been made in this subject, and so ample is the literature devoted to it, that no department of geology, it might be thought, has been more abundantly and successfully explored. Yet if we look through the pile of memoirs, articles and books,

[1] See an interesting and suggestive paper by Prof. Le Conte on "Critical Periods in the History of the Earth," *Bull. Dept. Geology, University of California*, vol. i. (1895), p. 313; also one by Prof. Chamberlin on "The Ulterior Basis of Time-divisions and the Classification of Geological History," *Journal of Geology*, vol. vi. (1898), p. 449.

we cannot but be struck with the predominant vagueness of their statements, and with the general absence of such numerical data determined by accurate, systematic and prolonged measurement as would alone furnish a satisfactory basis for computations of the rate at which denudation takes place. Some instrumental observations of the greatest value have indeed been made, but, for the most part, observations of this kind have been too meagre and desultory.

A little consideration will show that in all branches of the investigation of denudation opportunities present themselves on every side of testing, by accurate instrumental observation and measurement, the rate at which some of the most universal processes in the geological *régime* of our globe are carried on.

It has long been a commonplace of geology that the amount of the material removed in suspension and solution by rivers furnishes a clue to the rate of denudation of the regions drained by the rivers. But how unequal in value, and generally how insufficient in precision, are the observations on this topic! A few rivers have been more or less systematically examined, some widely varying results have been obtained from the observations, and while enough has been obtained to show the interest and importance of the method of research, no adequate supply of materials has been gathered for the purposes of accurate deduction and generalisation. What we need is a carefully organised series of observations carried out on a uniform plan, over a sufficient number of years, not for one river only, but for all the important rivers of a country, and indeed for all the greater rivers of each continent. We ought to know as accurately as possible the extent of the drainage-area of each river, the relations of river-discharge to rainfall and to other meteorological as well as topographical conditions; the variation in the proportions of mechanical and chemical impurities in the river-water according to geological formations, form of the ground, season of the year and climate. The whole geological *régime* of each river should be thoroughly studied. The admirable report of Messrs. Humphreys and Abbot on the "Physics and Hydraulics of the Mississippi," published in 1861, might well serve as a model for imitation, though these observers necessarily occupied themselves with some questions which are not specially geological and did not enter into others on which, as geologists, we should now gladly have further information.

Again, the action of glaciers has still less been subjected to prolonged and systematic observation. The few data already obtained are so vague that we may be said to be still entirely ignorant of the rate at which glaciers are wearing down their channels and contributing to the denudation of the land.

The whole of this inquiry is eminently suitable for combined research. Each stream or glacier, or each well-marked section of one, might become the special inquiry of a single observer, who would soon develop a paternal interest in his valley and vie with his colleagues of other valleys in the fulness and accuracy of his records.

Nor is our information respecting the operations of the sea much more precise. Even in an island like Great Britain, where the waves and tides effect so much change within the space of a human life-time, the estimates of the rate of advance or retreat of the shore-line are based for the most part on no accurate determinations. It is satisfactory to be able to announce that the Council of this Association has formed a committee for the purpose of obtaining full and accurate information regarding alterations of our coasts, and that with the sanction of the Lords of the Admiralty, the co-operation of the coast-guard throughout the three kingdoms has been secured. We may therefore hope to be eventually in possession of trustworthy statistics on this interesting subject.

The disintegration of the surface of the land by the combined agency of the subaërial forces of decay is a problem which has been much studied, but in regard to whose varying rates of advance not much has been definitely ascertained. The meteorological conditions under which it takes place differ materially according to latitude and climate, and doubtless its progress is equally variable. An obvious and useful source of information in regard to atmospheric denudations is to be found in the decay of the material of buildings of which the time of erection is known, and in dated tombstones. Twenty years ago I called attention to the rate at which marble gives way in such a moist climate as ours, and cited the effects of subaërial waste as these can be measured on the monuments of our graveyards and cemeteries (*Proc. Roy. Soc. Edin.*, vol. x. 1879-80, p. 518). I would urge upon town geologists, and those in the country who have no opportunities of venturing far afield, that they may do good service by careful scrutiny of ancient buildings and monuments. In the churchyards they will find much to occupy and interest them, not, however, like Old Mortality, in repairing the tombstones, but in tracing the ravages of the weather upon them, and in obtaining definite measures of the rate of their decay.

The conditions under which subaërial disintegration is effected in arid climates, and the rate of its advance, are still less known, seeing that most of our information is derived from the chance observations of passing travellers. Yet this branch of the subject is not without importance in relation to the denudation, not only of the existing terrestrial surface, but of the lands of former periods, for there is evidence of more than one arid epoch in geological history. Here, again, a diligent examination of ancient buildings and monuments might afford some, at least, of the required data. In such a country as Egypt, for instance, it might eventually be possible to determine from a large series of observations what has been the average rate of surface-disintegration of the various kinds of stone employed in human constructions that have been freely exposed to the air for several thousand years.

Closely linked with the question of denudation is that of the deposition of the material worn away from the surface of the land. The total amount of sediment laid down must equal the amount of material abstracted, save in so far as the soluble portions of that material are retained in solution in the sea. But we have still much to learn as to the conditions, and especially as to the rate, of sedimentation. Nor does there appear to be much hope of any considerable increase to our knowledge until the subject is taken up in earnest as one demanding and justifying a prolonged series of well-planned and carefully executed observations. We have yet to discover the different rates of deposit, under the varying conditions in which it is carried on in lakes, estuaries, and the sea. What, for instance, would be a fair average for the rate at which the lakes of each country of Europe are now being silted up? If this rate were ascertained, and if the amount of material already deposited in these basins were determined, we should be in possession of data for estimating, not only the probable time when the lakes will disappear, but also the approximate date at which they came into existence.

But it is not merely in regard to epigene changes that further more extended and concerted observation is needed. Even among subterranean movements there are some which might be watched and recorded with far more care and continuity than have ever been attempted. The researches of Prof. George Darwin and others have shown how constant are the tremors, minute but measurable, to which the crust of the earth is subject (*Report Brit. Assoc.*, 1882, p. 95). Do these phenomena indicate displacements of the crust, and, if so, what in the lapse of a century is their cumulative effect on the surface of the land?

More momentous in their consequences are the disturbances which traverse mountain-chains and find their most violent expression in shocks of earthquake. The effects of such shocks have been studied and recorded in many parts of the world, but their cause is still little understood. Are the disturbances due to a continuation of the same operation which at first gave birth to the mountains? Should they be regarded as symptoms of growth or of collapse? Are they accompanied with even the slightest amount of elevation or depression? We cannot tell. But these questions are probably susceptible of some more or less definite answer. It might be possible, for instance, to determine with extreme precision the heights above a given datum of various fixed points along such a chain as the Alps, and by a series of minutely accurate measurements to detect any upward or downward deviation from these heights. It is quite conceivable that throughout the whole historical period some deviation of this kind has been going on, though so slowly, or by such slight increments at each period of renewal, as to escape ordinary observation. We might thus learn whether, after an Alpine earthquake, an appreciable difference of level is anywhere discoverable, whether the Alps as a great mountain-chain are still growing or are now subsiding, and we might be able to ascertain the rate of the movement. Although changes of this nature may have been too slight during human experience to be ordinarily appreciable, their very insignificance seems to me to supply a strong reason why they should be sought for and carefully measured. They would not tell us, indeed, whether a mountain-chain was called into being in one gigantic convulsion,

or was raised at wide intervals by successive uplifts, or was slowly elevated by one prolonged and continuous movement. But they might furnish us with suggestive information as to the rate at which upheaval or depression of the terrestrial crust is now going on.

The vexed questions of the origin of raised beaches and sunk Forests might in like manner be elucidated by well-devised measurements. It is astonishing upon what loose and untrustworthy evidence the elevation or depression of coast-lines has often been asserted. On shores where proofs of a recent change of level are observable it would not be difficult to establish by accurate observation whether any such movements are taking place now, and, if they are, to determine their rate. The old attempts of this kind along the coasts of Scandinavia might be resumed with far more precision and on a much more extended scale. Methods of instrumental research have been vastly improved since the days of Celsius and Linnæus. Mere eye-observations would not supply sufficiently accurate results. When the datum-line has been determined with rigorous accuracy, the minutest changes of level, such as would be wholly inappreciable to the senses, might be detected and recorded. If such a system of watch were maintained along coasts where there is reason to believe that some rise or fall of land is taking place, it would be possible to follow the progress of the movement and to determine its rate.

But I must not dwell longer on examples of the advantages which geology would gain from a far more general and systematic adoption of methods of experiment and measurement in elucidation of the problems of the science. I have referred to a few of those which have a more special bearing on the question of geological time, but it is obvious that the same methods might be extended into almost every branch of geological dynamics. While we gladly and gratefully recognise the large amount of admirable work that has already been done by the adoption of these practical methods, from the time of Hall, the founder of experimental geology, down to our own day, we cannot but feel that our very appreciation of the gain which the science has thus derived increases the desire to see the practice still further multiplied and extended. I am confident that it is in this direction more than in any other that the next great advances of geology are to be anticipated.

While much may be done by individual students, it is less to their single efforts than to the combined investigations of many fellow-workers that I look most hopefully for the accumulation of data towards the determination of the present rate of geological changes. I would therefore commend this subject to the geologists of this and other countries as one in which individual, national and international co-operation might well be enlisted. We already possess an institution which seems well adapted to undertake and control an enterprise of the kind suggested. The International Geological Congress, which brings together our associates from all parts of the globe, would confer a lasting benefit on the science if it could organise a system of combined observation in any single one of the departments of inquiry which I have indicated or in any other which might be selected. We need not at first be too ambitious. The simplest, easiest and least costly series of observations might be chosen for a beginning. The work might be distributed among the different countries represented in the Congress. Each nation would be entirely free in its selection of subjects for investigation, and would have the stimulus of co-operation with other nations in its work. The Congress will hold its triennial gathering next year in Paris, and if such an organisation of research as I have suggested could then be inaugurated a great impetus would thereby be given to geological research, and France, again become the birthplace of another scientific movement, would acquire a fresh claim to the admiration and gratitude of geologists in every part of the globe.

---

## SECTION D.

### ZOOLOGY.

OPENING ADDRESS BY ADAM SEDGWICK, M.A., F.R.S., PRESIDENT OF THE SECTION.

*Variation and some Phenomena connected with Reproduction and Sex.*

IN the following Address an attempt is made to treat the facts of variation and heredity without any theoretical preconceptions. The ground covered has already been made familiar to us by the writings of Darwin, Spencer, Galton, Weismann, Romanes and others. I have not thought it advisable to discuss the theories of my predecessors, not from a want of appreciation of their value, but because I was anxious to look at the facts themselves and to submit them to an examination which should be as free as possible from all theoretical bias.

Zoology is the science which deals with animals. Knowledge regarding animals is, for convenience of study, classified into several main branches, amongst the most important of which may be mentioned: (1) the study of structure; (2) the study of the functions of the parts or organs; (3) the arrangement of animals in a system of classification; (4) the past history of animals; (5) the relations of animals to their environment; (6) the distribution of animals on the earth's surface. That part of the science of zoology which deals with the functions of organs, particularly of the organs of the higher animals, is frequently spoken of as physiology, and separated more or less sharply from the rest of zoology under that heading. So strong is the line of cleavage between the work of the physiologist and that of other zoologists, that this Association has thought it advisable to establish a special Section for the discussion of physiological subjects, leaving the rest of zoology to the consideration of the old established Section, D. In calling attention to this fact, I do not for one moment wish to question the advisability of the course of action which the Association has taken. The science of physiology in its modern aspects includes a vast body of facts of great importance and great interest which no doubt require separate treatment. But what I do wish to point out is that it is quite impossible for us here to abrogate all our functions as physiologists Some of the most important problems of the physiological side of zoology still remain within the purview of this Section.

For instance, the important and far-reaching problems connected with reproduction and variation are very largely left to this Section, and that large group of intricate and almost entirely physiological phenomena connected with the adaptations of organisms to their environment are dealt with almost exclusively here. Indeed, we may go further, and say that apart altogether from practical questions of convenience, which make it desirable to separate a part of physiological work from the Zoological Section, it is, as a matter of fact, impossible to divorce the intelligent study of structure from that of function. The two are indissolubly connected together. The differentiation of structure involves the differentiation of function, and the differentiation of function that of structure. The conceptions of structure and function are as closely associated as those of matter and force. A zoologist who confined himself to the study of the structure of organisms, and paid no attention to the functions of the parts, would be as absurd a person as a philologist who studied the structure of words and took no account of their meaning. In the early part of this century, when the subject-matter of zoology was not so vast as it is at present, this aspect of the case was fully recognised, and one of the greatest zoologists of the century, whether considered from the point of view of modern anatomy, or of modern physiology, was Professor of Anatomy and Physiology at the University of Berlin.

Having said that much as to the various aspects of living nature, of natural history, if you like, which it falls within the province of this Section to deal with, I may now proceed to the subject of my address. And when I mention to you what that subject is, you will be able to make some allowance for the somewhat commonplace remarks with which I have treated you. For that subject, though it has its important morphological aspects, is in the main a physiological one; at any rate, no study which does not take account of the physiological aspect of it can ever hope to satisfy the intellect of man. The subject, then, to which I wish to draw your attention at the outset of our proceedings, is the great subject of Variation of Organisms.

As every one knows, there is a vast number of different kinds of organisms. Each kind constitutes a species, and consists of an assemblage of individuals which resemble one another more closely than they do other animals, which transmit their characteristics in reproduction and which habitually live and breed together. But the members of a species, though resembling one another more closely than they resemble the members of other species, are not absolutely alike. They present differences, differences which make themselves apparent

even in members of the same family, *i.e.* in the offspring of the same parents. It is these differences to which we apply the term *variation*. The immense importance of the study of variations may be judged from the fact that, according to the generally received evolution theory of Darwin, it is to them that the whole of the variety of living and extinct organisms is due. Without variation there could have been no progress, no evolution in the structure of organisms. If offspring had always exactly resembled their parents and presented no points of difference, each succeeding generation would have resembled those previously existing, and no change, whether backwards or forwards, could have occurred. This phenomenon of genetic variation forms the bedrock upon which all theories of evolution must rest, and it is only by a study of variations, of their nature and cause, that we can ever hope to obtain any real insight into the actual way in which evolution has taken place. Notwithstanding its importance, the subject is one which has scarcely received from zoologists the attention which it merits.

Though much has been written on the causes of variation, too little attention has of late years been paid to the phenomenon. Since the publication of Darwin's great work on the "Variation of Animals and Plants under Domestication," there have been but few books of first-rate importance dealing with the subject. The most important of these is Mr. William Bateson's work, entitled "Materials for the Study of Variation." I have no hesitation in saying that I regard this work as a most important contribution to the literature of the evolution theory. In it attention is called, with that emphasis which the subject demands, to the supreme importance of the actual study of variation to the evolutionist, and a systematic attempt is made to classify variations as they occur in nature. In preparing this book Mr. Bateson has performed a very real service to zoology, not the least part of which is that he has made a most effective protest against that looseness of speculative reasoning which, since the publication of the "Origin of Species," has marred the pages of so many zoological writers.

The variations of organisms may be grouped under two heads, according to their nature and source: (1) There are those variations which appear to have no relation to the external conditions, for they take place when these remain unchanged, *e.g.* in members of the same litter; they are inherent in the constitution of the individual. These we shall call constitutional variations, or as their appearance seems nearly always to be connected with reproduction, they may be called *genetic* (congenital, blastogenic) *variations*. (2) The second kind of variations are those which are caused by the direct action of external conditions. These variations constitute the so-called *acquired characters*.

My first object is to consider these two kinds of variations, their nature, their causes, and their results on subsequent generations, and to inquire whether there are any fundamental differences between them. In this connection it is of particular importance that we should inquire whether acquired modifications are transmitted in reproduction. As is well known, there are two schools of thought holding directly opposite views as to this matter. The one of these schools—the so-called Lamarckian school—holds that they may be transmitted as such in reproduction; the other school, on the other hand, maintains that acquired modifications affect only the individual concerned, and are not handed on as such in reproduction. That the decision of the matter is not only theoretically important, but also practically, is evident, for upon it depends the answer to the question whether mental or other facilities acquired by the laborious exercise of the individual are ever transmitted to the offspring—whether the facility which the individual acquires in resisting temptation makes it any easier for the offspring to do the same, whether the effects of education are cumulative in successive generations. To put the matter as Francis Galton has put it, Is nature stronger than nurture, or nurture than nature?

We have then two kinds of variation to consider: (1) genetic variation, (2) acquired modification. It is the former of these—namely, genetic variation—with which I wish primarily to deal. Let us examine more fully the mode of its occurrence.

### *Genetic Variation.*

Organised beings present, as you are aware, two main kinds of reproduction, the sexual and the asexual. These two kinds of reproduction present certain differences, of which the most important, and the only one which concerns us now, is the fact that genetic variation is essentially associated with sexual reproduction, and is rarely, if ever, found in asexual reproduction. In other words, whereas the offspring resulting from asexual reproduction as a rule exactly resemble the parent, they are always different from the parents in sexual reproduction. I am aware that I am treading on disputed ground. You will observe that I do not make the assertion that asexually produced offspring *always* exactly resemble the parent, and never present genetic variations. To say that would be going too far in the present state of our knowledge. Therefore I have put the matter less strongly, and merely assert that whereas asexual reproduction is on the whole characterised by identity between the offspring and the parent, sexual reproduction is always characterised by differences more or less marked between the two; and I reserve the question as to whether genetic variations are ever found in asexual reproduction for later consideration.

This modified form of the statement will, I think, be admitted on all hands, but before going on I will illustrate my meaning by reference to actual examples.

Asexual reproduction is a phenomenon comparatively rare in the animal kingdom, and when it does occur it is exceedingly difficult to investigate from this particular point of view. In the vegetable kindom, on the other hand, it is quite common. All, or almost all, plants possess this power, and in a very great many of them the result of its exercise can be fully followed out, and contrasted with that of sexual reproduction. Let us follow it out in the potato-plant. The potato can and does normally propagate itself asexually by means of its underground tubers. As you will know, if you take one of these and plant it, it gives rise to a plant exactly resembling the parent. If the tuber (seed as it is sometimes erroneously called) be that of the Magnum Bonum, it gives rise to a plant with foliage, flowers and tubers of the Magnum Bonum variety; if it be of the Snowdrop, the foliage, flowers, habit and tubers are totally different from the Magnum Bonum, and are easily identified as Snowdrops. In this way a favourable variety of potato can be reproduced to almost any extent with all its peculiarities of earliness or lateness, pastiness or mealiness, power of resisting disease and so forth. By asexual reproduction the exact facsimile of the parent may always be obtained, provided the conditions remain the same.

Now let us turn to the results of sexual reproduction—the seeds, *i.e.* the real seeds, which as you know are produced in the flowers, are the means by which sexual reproduction is effected. They are produced in great quantity by most plants, and when placed in the ground under the proper conditions they germinate and produce plants. But these plants do not resemble the parent. Try the seed of the Magnum Bonum potato, and raise plants from it. Do you think that any of them will be the Magnum Bonum with all its properties of keeping, resisting disease, and so forth? Not a bit of it. The probability is, that not one of your seedling plants will exactly reproduce the parents; they will all be different. Again, take the apple; if you sow the seed of the Blenheim Orange and raise young apple-trees, you will not get a Blenheim Orange. All your plants will be different, and probably not one will give you apples with the peculiar excellence of the parent. If you want to propagate your Blenheim Orange and increase the number of your trees, you must proceed by grafting or by striking cuttings, which are the methods by which such a tree may be asexually reproduced. And so on. Examples might be multiplied indefinitely. Every horticulturist knows that variety characterises seedlings, *i.e.* sexual offspring, whereas identity is found in slips, grafts and offsets, *i.e.* in asexual offspring; and that if you want to get a new plant you must sow seeds, while if you want to increase your stock of an old one you must strike cuttings, plant tubers or proceed in some analogous manner.

An apparent exception to this rule is afforded by so-called bud variation, but it is not certain that this is really an exception. In so far as these bud variations are not of the nature of acquired variations produced by a change of external conditions, and disappearing as soon as the old conditions are renewed, they are probably stages in the growth and development of the organism. That is to say, they are of the same nature as those peculiarities in animals which appear at a particular time of life, such as a single lock of hair of a different colour from the rest of the hair,[1] the change in colour of hair with growth,[2] the appearance of insanity or of epilepsy at a particular age. There

[1] Darwin, "Variation," vol. i. p. 449.

[2] As an example I may refer to the Himalayan rabbit; Darwin, "Variation," vol. i. p. 114.

is nothing more remarkable in a single bud on a tree departing from the usual character at a particular time of life, than in a particular hair of a mammal doing the same thing.

We have seen that, speaking broadly, genetic variation is connected with sexual reproduction, and it becomes necessary to examine this mode of reproduction a little more fully. What is the essence of sexual reproduction, and how does it differ from asexual? What I am now going to say applies generally to the phenomenon whether it occurs in plants or animals. Sexual reproduction is generally carried on by the co-operation of two distinct individuals—these are called the male and female respectively. They produce, by a process of unequal fission which takes place at a part of their body called the reproductive gland, a small living organism called the reproductive cell. The reproductive cell produced by the male is called in animals the spermatozoon, and is different in form from the corresponding cell produced by the female, and called in animals the ovum. The object with which these two organisms are produced is to fuse with one another and give rise to one resultant uninucleated organism or cell, which we may call the *zygote*. This process of fusion between the two kinds of reproductive cells, which are termed *gametes*, is called conjugation. The difference in structure between the male and female gamete is a matter of secondary importance only, and is connected with the primary function of coming into contact and fusing. The same may be said with regard to the so-called sexual differences of the parents of the two kinds of gametes, and to the powerful instincts which regulate their action. The conjugation of the male and female gamete, or the fertilisation of the ovum, as it is sometimes called, consists in the fusion of two distinct masses of protoplasm which are nearly always produced by different individuals. In the case of hermaphrodites, the term applied to organisms which produce both male and female gametes in the same individual, there is generally some arrangement which tends to prevent the male gamete from conjugating with the female gamete of the same parent; but this phenomenon is not absolutely excluded, and takes place as a normal phenomenon in many plants and possibly in some animals.

This fusion of the protoplasm of the two gametes gives us a uninucleated organism—for the fusion of the nuclei of the two gametes seems to be an essential part of the process—in which the potencies of the two gametes are blended. The *zygote*, as the mass formed of the fused gametes is called, is formed by the combination of two individualities, and is therefore essentially a new individuality, the characters of which will be different from the characters of both of the parents. This fact, which is not apparent in the zygote when first established, because the parts are hardly distinguishable by our senses, becomes obvious as soon as organs, with the appearance of which we are familiar, are formed. As a general rule this cannot be said to have occurred until what we call maturity has been nearly reached, because we are not familiar enough with the features of immature organisms to detect individual differences. But you may rest assured that such differences exist at all stages of growth from that of the uninucleated zygote till death. How the characters of the two parents will combine in the zygote it is impossible to predict, and the result is never the same even though the conjugations have been between gametes of identical origin. There may be an almost perfect mixture, the blending extending to even quite minute details; or the characters of the one parent may predominate—be prepotent, as we call it—over those of the other; or they may blend in such a way that the zygote offers characters found in neither parent. Or, finally, the features of one parent may come out at one stage of growth, those of the other at another stage. But, however the characters may blend, the product never exactly resembles the parents. The extent to which it differs from them is the measure of the variation.

To resume, it will be observed that in the method of reproduction sometimes called sexual two distinct processes occur. One of these is the real reproductive act, which consists in the production by fission of uninuclear individuals called gametes; the second is the fusion of the gametes to form the zygote. The gametes are of two kinds, and the reason of there being two kinds is intelligible when we consider the parts they have to play. The male gamete is nearly always endowed with locomotive power, and the female gamete is stored with food material to be used by the zygote in the first stages of growth. The destiny of these two uninucleated organisms is to fuse with one another, and so to give rise to a zygote which ultimately assumes the typical form of the species. As a general rule, the gametes have but a limited duration[1] of life unless they conjugate, and this is quite intelligible when we remember that they have no organs, *e.g.* digestive organs, suitable for the maintenance of life. It is rarely found that they have the power of assuming the form of their parent, unless they conjugate. This never happens in the case of the male gamete (at any rate in animals), and only rarely in that of the female. When it occurs—that is to say, when the ovum develops without conjugation—we call the phenomenon parthenogenesis. Parthenogenesis is found more commonly in Arthropods than in other groups, but it may be more common than is supposed.[2]

In sexual reproduction then, in addition to the real reproductive act, which is the division by fission of the parent into two unequal parts, the one of which continues to be called the parent, while the other is the gamete, there is the subsequent conjugation process. It is to this conjugation process that that important concomitant of sexual reproduction must be attributed, namely, genetic variation. We have thus traced genetic variation to its lair. We have seen that it is due to the formation of a new individuality by the fusion of two distinct individualities. We have also seen that in the higher animals it is always associated with the reproductive act.

Let us now take a wider survey and endeavour to ascertain whether this most important process, a process upon which depends the improvement as well as the degradation of races, ever takes place independently of the reproductive act. In the Metazoa, to which for our present purpose I allude under the term higher animals, conjugation never takes place except in connection with reproduction. It is impossible from the nature of the process that it should do so, as I hope to explain later on. But among the Protozoa, the simplest of all animals, it is conceivable that conjugation might take place apart from reproduction, and as a matter of fact it does do so. Let us now examine a case in which this occurs. Amongst the free-swimming ciliated Infusoria it frequently happens that two individuals become applied together, and that the protoplasm of their bodies becomes continuous. They remain in this condition of fusion for some days, retaining, however, their external form and not undergoing complete fusion. While the continuity lasts there is an exchange of living substance between the two bodies, in which exchange a bit of the nucleus of each participates. It thus happens that at the end of conjugation, when the two animals separate, they are both different from what they were at the commencement; each has received protoplasm and a nucleus from its fellow, and the introduced nucleus fuses as we know with the nucleus which has not moved. It would therefore appear that all the essential features of the conjugation process, as we learnt them in the case of the conjugation of the gametes in the Metazoa, are present, and it is impossible to doubt that we have here an essentially similar phenomenon. The phenomenon differs, however, from the conjugation first described in this interesting and important respect, that the two animals separate and resume their ordinary life. It is true that their constitution must have been profoundly changed, but they retain their general form. I say that the constitution of the exconjugates, as we may call them after they are separated, must be different from what it was before conjugation, but so far as I know no difference in structure corresponding with this difference in constitution has been recorded. I feel no sort of doubt, however, that structural differences, *i.e.* variations, will be detected when the exconjugates are closely scrutinised and compared with the animals before conjugation, and I would suggest that definite observations be made with a view to testing the point. Here, then, we have a case of conjugation entirely dissociated from reproduction. Other cases of a similar character are known among the Protozoa, though as a general rule the fusion between the conjugating organisms is complete and permanent. Among plants conjugation is generally associated with reproduction, but not always, for in certain fungi[3] fusion of hyphæ and consequent intermingling of protoplasm occurs, and is not followed by any

[1] Under favourable conditions, they may live a considerable time—*e.g.* the spermatozoon of certain ants, which are stated by Sir John Lubbock to live in some cases for seven years.

[2] It may be mentioned as a curious fact that parthenogenesis is rarely found in the higher plants, and, as I have said, is not known for the male gamete among animals.

[3] It must be mentioned, however, that in the case of these fungi the fusion of nuclei has not been observed, nor has it been noticed whether the habit, structure, or constitution of the conjugating plants are altered after the fusion.

form of reproduction. Among bacteria alone, so far as I know, has the phenomenon of conjugation never been observed.

To sum up, we have seen that the phenomenon of conjugation is very widely distributed. Excluding the bacteria, there is reason to believe that it forms a part of the vital phenomena of all organisms. Its essential features are a mixture and fusion of the protoplasm of two different organisms, accompanied by a fusion of their nuclei. It results in the formation of a new individuality, which differs from the individualities of both the conjugating organisms. This difference manifests itself in differences in habit, constitution, form, and structure, such differences constituting what we have called genetic variations.

The conjugation of the ovum and spermatozoon in the higher animals, and the corresponding process in the higher plants, are special cases of this conjugation, in which special conjugating individuals are produced, the ordinary individuals being physically incapable of the process. The phenomenon of sex, with all its associated complications, which is so characteristic of the higher animals and plants, is merely a device to ensure the coming together of the two gametes. In the lower animals, it is possible for the ordinary organism to conjugate; consequently the phenomenon does not form the precursor of developmental change, and is in no way associated with reproduction. Indeed, in such cases it is often the opposite of reproduction, inasmuch as it brings about a reduction in the number of individuals, two separate individuals fusing to form one.

### *Acquired Characters.*

We now come to the consideration of the second kind of variations—namely, those which owe their origin to the direct action of external agencies upon the particular organism which shows the variation; or, as Darwin puts it, to the definite action of external conditions. These are the variations which I have called acquired variations or acquired characters. This is not a good name for them, but at the present moment, when I am about to submit them to a critical examination, I do not know of any other which could be suitably applied. Later on, when I sum up the various effects of the direct action of external agencies upon the organism, I may be able to use a more suitable term.

The main peculiarities of acquired variations are two in number; (*a*) they make their appearance as soon as the organism is submitted to the changed conditions; (*b*) speaking generally, they are more or less the same in all the individuals of the species acted upon. As examples of this kind of variations, I may mention the effect of the sun upon the skin of the white man; the Porto Santo rabbit, an individual of which recovered the proper colour of its fur in four years under the English climate;[1] the change of *Artemia salina* to *Artemia milhausenii*; the increase in size of muscles as the result of exercise; and the development of any special facility in the central nervous system. Among plants, variations of this kind are very easily acquired, by altering the soil and climate to which the individuals are submitted. So common are they, that it is quite possible that a large number of species are really based upon characters of this kind; characters which are produced solely by the external conditions, and which frequently disappear when the old conditions are reverted to.

With regard to these variations, we want to ask the following question: Do they ever last after the producing cause of them is removed, and are they transmitted in reproduction? In a great number of cases they either cease when the cause which has produced them is removed, or if they last the life of the individual they are not transmitted in reproduction. But is this always the case? That is the important question we now have to consider.

But before doing so let us inquire what acquired characters really are. The so-called adults of all animals have, as part of their birthright, a certain plasticity in their capacity of reacting to external influences; they all have a certain power of acquiring bodily and mental characters under the influence of appropriate stimuli. This power varies in degree and in quality in different species. In plants, for instance, it is mainly displayed in habit of growth, form of foliage, &c.; in man, in mental acquirements, and so on. But however it is displayed, it is this property of organisms which permits of the acquisition of those modifications of structure which have been so widely discussed as *acquired* characters. Now this power, when closely considered, is in reality only a portion of that capacity for development which all organisms possess, and with which they become endowed at the act of conjugation. A newly formed zygote possesses a certain number of hidden properties which are not able to manifest themselves unless it is submitted to certain external stimuli. It is these stimuli which constitute the external conditions of existence, and the properties of the organism which are only displayed under their influence are what we call acquired characters. They are acquired in response to the external stimuli.

It would appear, then, that every feature which successively appears in an organism in the march from the uninucleated zygote to death is an acquired character. At first the stimuli which are necessary are quite simple, being little more than appropriate heat and moisture; later on they become more complicated, until finally, when the developmental period is over and the mature life begins, the necessary conditions attain their greatest complexity, and their fulfilment constitutes what we call in the higher animals education. Education is nothing more than the response of the nearly mature organism to external stimuli, the penultimate response of the zygote to external stimuli, the ultimate being those of senile decay, which end in natural death. Acquired properties, it will be seen, are really stages in the developmental history. They differ in the complexity of the stimulus required to bring them out. For instance, the segmentation of the egg requires little more than heat and moisture, the walking of the chick the stimulus of light and sound and gravity, the evolutions of an acrobat the same in greater complexity, and, lastly, the action of a statesman requires the stimulation of almost every sense in the greatest complexity. Moreover, not only are there differences in the complexity of the stimulus required, but also in the rapidity with which the organism reacts to it. The chick undergoes its whole embryonic development in three weeks, a man in nine months; the chick develops its walking mechanism in a few minutes, while a man requires twelve months or more to effect the same end. Chickens are much cleverer than human beings in this respect. There is the same kind of difference between them that there is between the power of learning displayed by a Macaulay and that displayed by a stupid child.

An instinct is nothing more than an internal mechanism which is developed with great rapidity in response to an appropriate stimulus. It is difficult for us to understand instincts, because with us almost all developmental processes are extremely slow and gradual. This particularly applies to the development of those nervous mechanisms, the working of which we call reason.

Within certain limits the external conditions may vary without harming the organism, but such variations are generally accompanied by variations in the form in which the properties of the zygote are displayed. If the variations of the conditions are too great, their action upon the organism is injurious, and results in abortions or death. And in no case can the external conditions call out properties with which the zygote was not endowed at the act of conjugation.

It would thus appear that acquired characters are merely phases of development; they are the manifestations of the properties of the zygote, and are called forth only under appropriate stimulation; moreover, they are capable of varying within certain limits, according to the nature of the stimulus, and it is to these variations that the term acquired character has been ordinarily applied.

A genetic character, on the other hand, is the possibility of acquiring a certain feature under the influence of a certain stimulus; it is not the feature itself—that is an acquired character—but it is the possibility of producing the feature. Now as the possibility of producing the feature can only be proved to exist by actually producing it, the term genetic character is frequently applied to the feature itself, which is, as we have seen, an acquired character. In consequence of this fact, that we can only determine genetic characters by examining acquired characters, a certain amount of confusion may easily arise, and has indeed often arisen, in dealing with this subject. This can be avoided by remembering that in describing genetic characters account must always be taken of the conditions. For example, the white fur of the Arctic hare is an acquired character, acquired in response to a certain stimulus; while the power of so responding to the particular stimulus when applied at the correct time is a genetic character. Thus a genetic character is a character which depends upon the nature of the organism,

[1] Darwin, "Variation," ed. 2, vol. i. p. 119.

hile an acquired character depends on the nature of the stimulus.

If we imagine a zygote to be a machine capable of working out certain results on material supplied to it, then we should properly apply the term genetic character to the features of the machinery itself, and the words acquired character to the results achieved by its working. These clearly will depend primarily on the structure of the machinery, and secondarily upon the material and energy supplied to it—that is to say, upon the way in which it is worked.

Variations in genetic characters are variations in the machinery of different zygotes—that is to say, in the constitution—while variations in acquired characters are variations in the results of the working of one zygote according to the conditions under which it is worked.

For instance, let us take the case of those twins which arise by the division of one zygote, and are consequently identical in genetic characters, *i.e.* in constitution. If they are submitted to different conditions, they will develop differences which will depend entirely upon the conditions and the time of life when the differentiation in the conditions occurred. These differences, then, will be a function of the external conditions, *i.e.* of the manner in which the machinery is worked, and constitute what we call variation in acquired characters.

### *Are Acquired Characters Transmissible as such in Reproduction?*

To return to our question, are the so-called acquired characters ever transmitted in reproduction? Let us consider what this question means in the light of the preceding discussion. Acquired characters are features which arise in the zygote in response to external stimuli. Now the zygote at its first establishment has none of the characters which are subsequently acquired. All it has is the power of acquiring them. Clearly, then, acquired characters are not transmitted. The power of producing them is all that can be transmitted; and this power resides in the reproductive organs and in the gametes to which the reproductive organs give rise, so that the question must be put in another form. Is it possible by submitting an organism to a certain set of conditions, and thus causing it to acquire certain characters, so to modify its reproductive organs that the same characters will appear in its offspring as the result of the application of a different and simpler stimulus?

For instance, the power of reading conferred by education, the hardness of the hands and increased size of the muscles produced by manual labour: is it possible that these characters, now produced by complex external stimuli applied at a particular period of life, should ever in future ages be produced by the simpler stimuli found within the uterus, so that a man may be born able to read or write, or with hands horny and hard like those of a navvy?

In trying to find an answer to this question let us first of all look into the probabilities of the case, to see if we can relate the question to any other class of phenomena about which we have, or think we have, definite knowledge.

When an organism is affected by external agents the action may apply to the whole organisation or principally to one organ. Let us take a case in which one organ only appears to be affected, *e.g.* the enlargement by exercise of the right arm of a man. Now, although in this case it is only the muscles of the arm which appear at first sight to be affected, we must not forget that the organs of the body are correlated with one another, and an alteration of one will produce an alteration in others. By exercise of the right arm the muscles of that arm are obviously enlarged, but other changes not so obvious must also have taken place. The bones to which the muscles are attached will be altered; the blood-vessels supplying the muscles will be enlarged, and the nerves which act upon the muscles, and probably the part of the central nervous system from which they proceed, will also be altered. These are some of the more obvious correlated changes which will have occurred; no doubt there will have been others—indeed it is not perhaps too much to say that all the organs of the body will have reacted to the enlargement of the arm—but the effect on organs not in functional correlation with the muscles of the right arm will be imperceptible, and may be neglected. Thus the colour of the hair, the length and character of the alimentary canal, size of the leg muscles, the renal organs, &c., will not show appreciable alteration. Above all, the other arm will not be affected, or if it is affected the alteration will be so slight as not to be noticeable. Now, we know that homologous parts, whether symmetrically homologous or serially so, are in some kind of close connection. For instance, when one member of an homologous series varies, it is commonly found that other members of the same series will also vary. Yet in spite of this connection which exists between the right and left arms and between the right arm and right leg, there is no similar alteration either in the left arm or in the right leg. Now, if parts which from these facts we may suppose to be in some connection are not affected, how can we expect the reproductive organs, not only to be modified, but also to be so modified that the germs which are about to be budded off from them will be so affected as to produce exactly the same character—in this case enlarged muscle, &c.—without the application of the same stimulus, viz. exercise? Thus, while I freely admit that every alteration of an organ in response to external agents will react through the whole organisation, affecting each organ in functional correlation with the affected organ in a way which will depend upon the function of the correlated organ, and possibly other organs not in functional correlation in an indefinite way and to a slight extent, yet I maintain that it is very hard to believe that it will have such a sharp and precise effect upon every spermatozoon and ovum subsequently produced that not merely will these products be altered generally in all their properties, but that one particular part of them—and that part of them always the same—will be so altered that the organisms which develop from them will be able to present the same modification on the application of a different stimulus. It is inconceivable; unless, indeed, we suppose that the very molecules of the incipient organs in the germ are more closely correlated with corresponding parts of the parent body than are the homologous parts of the parent body with one another.

Now, to prove the existence of such a remarkable and intimate correlation would surely require the very strongest and most conclusive evidence. Is there any such strong evidence? I think I may fairly answer this question in the negative. The evidence which has been brought forward in favour of the so-called inheritance of acquired characters is far from conclusive. That such evidence[1] exists I do not deny, but it is all, or almost all, capable of receiving other interpretations.

### *Effect of Changed Conditions upon the Reproductive Organs.*

On the other hand, all the certain evidence we have concerning what happens when the reproductive organs are affected, either directly or by correlation, by a change of conditions—and, as we have seen above, they must be affected if there is to be any change in the offspring—tends to show that there is not any relation between the effect produced on the parent and that appearing in the offspring.

The only means of judging whether the reproductive organs are affected by external conditions is by observing any change which may occur in their function. Now, only two such physiological effects of a change of conditions are certainly known; these are (1) the production of sterility or of partial sterility; (2) the production of an increased but indefinite variability in the offspring. With regard to the first of these effects: One of the most common, or at any rate one of the most noticeable, alterations in an organism, effected by change in the external conditions, is an alteration of the reproductive system, an alterationof such a kind that organisms which had previously freely interbred with one another are no longer able to do so. One of the most common results of removing organisms from their natural surroundings is to induce sterility or partial sterility. There is no reason to doubt that this sterility or tendency to sterility is, broadly speaking, due to an affection of the reproductive system. In the case of the higher animals, it may in some cases be due to an action upon the instincts, but in the lower animals and in plants we can hardly doubt that it is due to a direct action upon the reproductive organs. Indeed in plants these organs are often visibly affected. Among animals, however, there does not appear to be any satisfactory evidence on the point, and it is not known what organs are affected, whether it is the actual gametes, or the reproductive glands, or some of the other organs concerned.[2]

The other result of changed conditions which is certainly known is to induce an increased amount of variability of the genetic kind, though not immediately, often indeed not until

[1] For a good statement and discussion of the evidence in favour of this view, see Romanes' "Darwin and after Darwin," vol. ii. chaps. 3 and 4.

[2] The exact cause of this sterility in the higher animals is a point which specially needs investigation.

after the lapse of some generations. On this point Darwin says: "Universal experience shows us that when new flowers are first introduced into our gardens they do not vary; but ultimately all, with the rarest exceptions, vary to a greater or less extent" ("Variation," 2, p. 249)[1] With regard to the variability thus induced, it is to be noticed that it is not confined to any particular organ, nor does it show itself in any particular way. On the contrary, the whole organisation is affected, and the variations are quite indefinite.

To sum up the argument as it at present stands: (1) a change in conditions cannot affect the next generation unless the reproductive organs are affected; (2) from a consideration of the facts of the case, it is almost inconceivable that the effect produced upon any organ of a given organism by a change of conditions should so modify the reproductive organs of that organism as to lead to a corresponding modification in the offspring without the latter being exposed to the same conditions; (3) the only effects, which are certainly known, of changed conditions upon the reproductive organs are (*a*) the production of sterility; (*b*) an increase in genetic variability.

As far, then, as our certain knowledge goes, it would appear that a change of conditions may have one or both of the following effects:—

(1) A definite change, of the same character, or nearly so, in all the individuals acted upon. Such changes may be adaptive or non-adaptive, but they are not permanent, lasting only so long as the change of conditions, or at most during the life of the individual acted upon. They are not transmitted in reproduction, and do not appear in the offspring unless it is submitted to the same conditions. These variations are the direct result of the action of the environment upon the individual, with the exception of the reproductive organs.

(2) Increase in the variations of the genetic kind These are seen, not in the generation[2] first submitted to the changed condition, but in the next or some subsequent generations. The effect is produced through the reproductive organs. These variations are non-adaptive, and different in each individual.

If the reproductive organs are affected we get an increase in the variations of the genetic kind. These, we have seen, are usually of an indefinite character; they are different in every case, and their nature cannot be predicted from experience. But we still have to ask: Is this is a universal rule? Does it never happen that a change of conditions so affects the reproductive organs as to produce a definite non-adaptive change of the same character or nearly so in all the descendants of the individual acted upon? This is the most obscure question connected with the study of variations. If such changes occur, they might be cumulative, being increased in amount by the continued action of the conditions. They would be non-adaptive, their nature depending on the constitution of the reproductive cells and having no functional relation to the original stimulus.

As possible examples of such variation, I may recall those variations referred to by Darwin as 'fluctuating variations which sooner or later become constant through the nature of the organism and of surrounding conditions, but not through natural selection" ("Origin," ed. 6, p. 176); to the variations in turkeys and ducks which take place as the result of domestication ("Variation," 2, p. 250); to those variations which Darwin had in his mind when he wrote the following sentence ("Origin," p. 72): "There can be little doubt that the tendency to vary in the same manner has often been so strong that all the individuals of the same species have been similarly modified without the aid of selection."

It is, however, as I have said, extremely doubtful if variations of this kind really occur. The appearance of them may be caused by the combination of the two other kinds of variation. In all cases which might be cited in support of their occurrence, there are the following doubtful elements: (1) no clear statement as to whether the variations showed themselves in the individuals first acted upon; (2) no history of the organisms when transported back to the old conditions.

[1] The phenomenon of increased variability following upon change of conditions has most often been observed when the change has been from a state of nature to a state of cultivation. Hence the conclusion has been drawn that the kind of change involved in domestication alone induces variation. But there is no evidence in favour of this view. The evidence shows that change of conditions in itself may induce greater variability.

[2] No doubt the individuals of the generation first submitted to the changed conditions would be affected as regards their reproductive organs, which would be altered in structure, but this has not been made out, though there are indications of such an effect in certain plants, *vide* Appendix.

Moreover, a general consideration of the facts of the case renders it improbable that such similar and definite genetic variations should often occur at any rate in sexual reproduction. For although the effect upon the reproductive organs may possibly be almost the same in nearly all the individuals acted upon, it must not be forgotten that the reproductive elements have to combine in the act of conjugation, and that it is the essence of this act to produce products which differ in every case.

*Effect of Changed Conditions in Asexual Reproduction.*

This brings us to the consideration of the question reserved on p. 503: Are genetic variations ever found in asexual reproduction?

If the views expressed in the earlier part of this address are correct, it would seem to follow that genetic variations are variations in the actual constitution, and are inseparably connected with the act of conjugation. The act of conjugation gives us a new constitution, a new individuality, and it is the characters of this new individual in so far as they differ from the characters of the parents which constitute what we have called genetic variations. According to this, the answer to our question would be that genetic variations cannot occur in asexual reproduction, and that if any indefinite variability recalling genetic variability makes its appearance[1] it must be part of the genetic variability and directly traceable to the zygote from which the asexual generations started.

But if genetic variability is not found in asexual reproduction, the question still remains, Can the other kind of variations—namely, those due to the direct action of external forces upon the organism—be transmitted in asexual reproduction? Now we have already seen that the effect of external agencies acting upon the organism must be regarded under two heads, according as to whether the reproductive organs are or are not affected. If the reproductive organs are not affected, then variations caused by the impact of external forces will not be transmitted; if, on the other hand, they are affected, the next generation will show the effect. We have further seen that in the case of sexual reproduction a modification of the reproductive organs will, because of the intervention of conjugation, appear as an increase in genetic variability only. How will the matter stand in the case of asexual reproduction? First, with regard to modifications which do not affect the reproductive system—they, as in sexual reproduction, will not be transmitted. Secondly, as regards modifications which do affect the reproductive organs—they will be transmitted, *i.e.* they will affect the next generation; and the question arises, How will they be transmitted? For here we have the opportunity wanting in the case of sexual reproduction of studying the transmission of modifications of the reproductive system without the complications introduced by the act of conjugation.

In considering this matter, it must be remembered that the reproductive organs are, with regard to external influences, exactly as any other organ. They can be modified either directly or indirectly, though they are in animals often less liable to direct modification by reason of their internal position.[2] These modifications may, as in the case of other organs, be obvious to the eye of the observer, or they may be so slight as only to be detected by an alteration of function. Now, in the case of the reproductive organs this alteration of function will show itself in the individuals of the next generation (if not before) which proceed directly and without any complication from the affected tissue. How will these individuals be affected? Will they all be affected in the same kind of way or will they they be affected in different ways? Finally, will the modi-

[1] Weismann, "On Heredity," vol. ii. English edition, p. 161. Warren E., "Observation on Heredity in Parthenogenesis," *Proc. Roy. Soc.*, 65, 1899, p. 154. These are the only observations I know of on this subject. They tend to show the presence of a slight variability, but they are not entirely satisfactory. In connection with this matter, I may refer to Weismann's view that *Cypris reptans*, the species upon which his observations were made, reproduces entirely by parthenogenesis, and has lost the power of sexual reproduction. This view is based on the fact that he has bred forty consecutive parthenogenetic generations and has never seen a male. As Weismann bases some important conclusions on this view, with regard to the importance of conjugation in rejuvenescence of organisms, I may point out that the fact that he has bred forty successive generations and has never seen a male cannot be regarded as conclusive evidence that males never appear. We know of many cases in which reproduction can continue for more than forty generations without the intervention of conjugation, *e.g.* ciliated infusoria, many plants, and of other species of crustacea in which the male is very rare and only appears after long intervals.

[2] How far the abnormal position of the testes of mammalia may receive its explanation in this connection is a question worthy of consideration.

fication last their lives only, or will it continue into subsequent asexually produced generations?

Let us endeavour to answer these questions:—

(1) How will the offspring be affected? That will depend entirely upon how the reproductive organ was affected. Will the modification in the offspring have an adaptive relation whatever to the external cause? Now here we have a capital opportunity, an opportunity not afforded at all by sexual reproduction, of examining by experiment and observation the Lamarckian position. My own opinion is that there will be no relation of an adaptive kind between the external cause and the modification of the offspring. For instance, let us imagine, as an experiment, that a number of parthenogenetically reproducing organisms are submitted to a temperature lower than that at which they are accustomed to live. Let us suppose that the cold affects their reproductive organs and produces a modification of the offspring. Will the modification be in the direction of enabling the offspring to flourish in a lower temperature than the parent? My own opinion, as I have said, is that there will probably be no such tendency in the offspring, if all possibility of selection be excluded. But that is only an opinion. The question is unsettled, and must remain unsettled until it is tested upon asexually reproducing organisms.

(2) Will they all be affected in the same kind of way? Yes, presumably they will. I arrive at this conclusion, not by experiment, but by reasoning from analogy. In the case of other organs of the body, the same external cause produces in all individuals acted upon, roughly speaking, the same kind of effect, *e.g.* action of sun upon skin, effect of transplanting maize, Porto Santo rabbits, &c. The question, however, cannot be settled in this way. It requires an experimental answer

(3) Will the modification last beyond the life of the individuals produced by the affected reproductive organ? I can give no answer to this question. We have no data upon which to form a judgment. We cannot say whether it is possible permanently to modify the constitution of an organism in this way, or whether, however strong the cause may be, consistently of course with the non-destruction of life, the effects will gradually die away—it may be in one, it may be in two or more generations. There are cases known which might assist in settling these questions, but I must leave to another opportunity the task of examining them. I refer to such cases as *Artemia salina*, various cases of bud variation which cannot be included under the head of growth variation.

### *Senile Decay and Rejuvenescence of Organisms.*

Another question, also of the utmost importance, confronts us at this point. As is well known, organisms are liable to wear and tear, sooner or later some part or parts essential to the maintenance of the vital functions wear out and are not renewed by the reparative processes which are supposed to be continually taking place in the organism. This constitutes what we call senile decay, and leads to the death of the organism. As a good example of the kind of cause of senile decay, we may mention the wearing out of the teeth, which in mammals at any rate are not replaced; the wearing out of the elastic tissue of the arterial wall, which is probably not replaced. There is no reason to suppose that the reparative process of any organism is sufficiently complete to prevent senile decay. There is probably always some part or parts which cannot be renewed, even in the simplest organisms. Maupas has shown that this holds for the ciliated Infusoria, and he has also shown how the renewal of life, which of course must be effected if the species is to continue, is brought about. He has shown that it is brought about by conjugation, during which process the organism may be said to be put into the melting-pot and reconstituted. For instance, many of the parts of the conjugating individuals are renewed, including the whole nuclear apparatus, which there is every reason to believe is of the greatest importance to living matter.

On reconsidering the life of the Metazoa in light of the facts established by Maupas for the Infusoria, we see that all Metazoa are in a continual state of fission, as are the ciliated Infusoria. They are continually dividing into two unequal parts, one of which we call the parent and the other the gamete. The parent Metazoon must eventually die; it cannot be put into the melting-pot; its parts cannot be completely renovated. The gamete can be put into the melting-pot of conjugation, and give rise to an entirely reconstituted organism, with all the parts and organs brand new and able to last for a certain time, which is the length of life of the individual of the species.

Is there any other way than that of conjugation by which an organism can acquire a complete renewal of its organs? Is the renewal furnished by the development of all the parts afresh which takes place in a parthenogenetic ovum such a complete renewal? This question cannot now be certainly answered, but the balance of evidence is in favour of a negative answer. And this view of the matter is borne out by a consideration of the facts of the case. In all cases of conjugation which have been thoroughly investigated, the nuclear apparatus is completely renewed. It would appear, indeed, as though the real explanation of the uninuclear character of the Metazoon gamete is to be sought in the necessity of getting the nuclear apparatus into the simplest possible form for renewal. Now in the development of a parthenogenetic ovum the ordinary process of renewal of the nucleus is often in partial abeyance. As a rule, it only divides once instead of twice, and there is, of course, no reinforcement by nuclear fusion. It is, of course, possible that the reinforcement by nuclear fusion which occurs in conjugation may have a different explanation from the nuclear reconstitution which takes place in the formation of polar bodies and similar structures. On the other hand, it may all be part of the same process. We cannot tell. So that we are unable to answer the question whether for complete rejuvenescence a new formation of all parts of the organism is sufficient, or whether a reconstitution of the nuclear apparatus of the kind which takes place in the maturation of the Metazoon ovum and the division of the micro-nucleus of Paramœcium is also required; or, finally, whether in addition to the latter phenomenon a reinforcement and reconstitution by fusing with another nucleus is also necessary for that complete rejuvenescence which enables an organism to begin the life cycle again and to pass through it completely.

With regard to buds in plants, there is reason to believe that they share in the growing old of the parent. That is to say, if we suppose the average life of the individual to be 100 years, a bud removed at 50 will be 50 years of age, and only be able to live on the graft for 50 more years.

### *Heredity.*

Having now spoken at some length o. the phenomenon of variation, I must proceed to consider from the same general point of view the phenomenon of heredity.

As we have seen, in asexual reproduction heredity appears, as a general rule, if not always, to be complete. The offspring do not merely present resemblances to the parent—they are identical with it. And this fact does not appear to be astonishing when we consider the real nature of the process. Asexual reproduction consists in the separation off of a portion of the parent, which, like the parent, is endowed with the power of growth. In virtue of this property it will assume, if it does not already possess it, and if the conditions are approximately similar, the exact form of the parent. It is a portion of the parent; it is endowed with the same property of growth; the wonder would be if it assumed any other form than that of the parent. Indeed, it is doubtful if the word heredity would ever have been invented if the only form of increase of organisms was the asexual one, because there being no variation to contrast with it, it would not have struck us as a quality needing a name, any more than we have a name for that property of the number two which causes it to make four when duplicated.

The need for the word heredity only becomes apparent when we consider that other form of reproduction in which the real act of reproduction is associated with the act of conjugation. Looking at reproduction from a broad point of view, we may sum up the difference between the two kinds, the sexual and the asexual, by saying that, whereas the essence of sexual reproduction is the formation of a new individuality, asexual reproduction merely consists in increasing the number of one kind of individual. From this point of view sexual reproduction is better termed the creation of a new individuality, for that, and not the increase in the number of individuals, is its real result. Inasmuch as conjugation of two organisms is the essential feature of sexual reproduction, it would appear that the number of individuals would be actually diminished as a result of it; and this does really happen, though in a masked manner, for we are not in the habit of looking upon the spermatozoon and ovum as individuals, though it is absurd not to do so, as they contain latent all the properties of the species, and are sometimes able to manifest these properties (parthenogenetic ova) without conjugating. In some of the lower organisms the fact that conjugation does not result in an increase of the number of

individuals, but only in the production of a new individuality, is quite apparent, for in them two of the ordinary individuals of the species fuse to form one (many Protozoa).

So that sexual reproduction gives us a new individuality which can spread to almost any extent by asexual reproduction. This asexual reproduction gives us a group of organisms which is quite different from a group of organisms produced by sexual reproduction. Whereas the latter groups constitute what we call species, the former group has, so far as I know, no special name, unless it be variety; but variety is not a satisfactory name, for it has been used in another sense by systematisers.

Heredity, then, is really applicable only to the appearance in a zygote of some of the properties of the gametes. A zygote has this property of one of the precedent gametes, and that property of the other, in virtue of the operation of what we call heredity; it has a third property possessed by neither of the precedent gametes in virtue of the action of variation, the nature of which we have already examined. It is impossible to say which property of a gamete will be inherited, and it is impossible to predict what odd property will result from the combination of the properties of the two gametes. Of one thing only are we certain, that they are never the same in zygotes formed by gametes produced in immediate succession from the same parent.

We may thus regard the activities of the zygote as the resultant of the dashing together of the activities of the gametes.

Conjugation, then, is a process of the utmost importance in biology; it provides the mechanism by which organisms are able to vary, independently of the conditions in which they live. It lies, therefore, at the very root of the evolution problem; the power of combining to form a zygote is one of the fundamental properties of living matter.

*Species.*

Now let us consider one of the effects of this property upon organisms. The effect to which I refer is the division of animals into groups called species. Species are groups of organisms the gametes of which are able to conjugate and produce normal zygotes. Now in nature there appear to be many causes which prevent gametes from conjugating. First and most important of all is some physical incompatibility of the living matter which prevents that harmonious blending of the two gametes which is essential for the formation of a normal zygote. Very little is known as to the real nature of this incompatibility; in fact, it is hardly an exaggeration to say that nothing is known. It may be that there is actual repulsion between the gametes, or it may be, in some cases, at least, that the gametes are able to fuse, but not to undergo that intimate blending which is necesary for the production of a perfect zygote. In some cases we know that something like this happens; for instance, a blend can be obtained between the horse and the ass, but it is not a perfect blend, the product or zygote being imperfect in one most important particular—namely, reproductive power.

A second cause which prevents conjugation is a purely mechanical one—viz. some obstacle which prevents the two gametes from coming together. As an instance of this I may refer to those cases amongst plants in which conjugation is impossible, because the pollen tube is not long enough to reach the ovule. In yet other cases conjugation is impossible because the organisms are isolated from one another either geographically or in consequence of their habits. There are probably many causes which prevent conjugation, but, whatever they may be, the effect of them is to break up organisms into specific groups, the gametes of which do normally conjugate with one another.

In many cases, no doubt, the gametes of organisms which are kept apart in nature by mechanical barriers will conjugate fully if brought together. But in the great majority of cases it is probable no amount of proximity will bring about complete conjugation. There is physical incompatibility. Here is a fruitful opening for investigation. Observations are urgently needed as to the real nature of this incompatibility.

*Importance of the Study of Variation.*

Another and most important effect of conjugation is, as we have seen, the much-spoken-of constitutional or genetic variations. They are, as we have already insisted, of the utmost importance to the evolutionist. Evolution would have been impossible without them, for it is made up of their summation. It becomes, therefore, desirable to find out to what extent a species is capable of varying. This can only be done, as Mr. Bateson has pointed out, by recording all variations found. Mr. Bateson, in his work already referred to, has carried this out, and has shown the way to a collection of these most important data. In order to carry it further, I would suggest that the collection be made, not only for structure, but also for function. This has been done largely for the nervous functions by psychologists and naturalists who pay special attention to the instincts of animals; but we want a similar collection for other functions. For instance, the variations in the phenomena of heat and menstruation, and of rut amongst mammals, and so on. To do this is really only to apply the methods of comparative anatomy and comparative physiology to the members of a species, as they have already been applied to the different species and larger groups of the animal kingdom. Such investigations cannot fail to be of the greatest interest. Indeed, when we have learnt the normal habits and structure of a species, what more interesting study can there be than the study of the possibilities of variation contained within it? Then, when we know the limits of variability of any given specific group, we proceed to try if we can by selective breeding or alteration of the conditions of life alter the variability, and perhaps call into existence a kind of variation quite different in character from that previously obtained as characteristic of the species.

*The Evolution of Heredity and the Origin of Variation.*

These remarks bring me to the consideration of a point to which I am anxious to call your attention, and which is an important aspect of our subject. Has the variability of organisms ever been different from what it is now? Has or has not evolution had its influence upon the property of organisms as it is supposed to have had upon their other properties? There is only one possible answer to this question. Undoubtedly the variability of organisms must have altered with the progress of evolution. It would be absurd to suppose that organisms have remained constant in this respect while they have undergone alteration in all their other properties. If the variability of organisms has altered, it becomes necessary to inquire in what direction has it altered? Has the alteration been one of diminution, or has it been one of increase? Of course, it is possible that there has been no general alteration in extent with the course of evolution, and that the alteration, on the whole, has been one of quality only. But passing over this third possibility, let us consider for the moment which of the two first-named alternatives is likely to have occurred.

According to the Darwinian theory of evolution, one of the most important factors in determining the modification of organisms has been natural selection. Selection acts by preserving certain favourable variations, and allowing others less favourable to be killed off in the struggle for existence. It thus will come about that certain variations will be gradually eliminated. Meanwhile the variations of the selected organisms will themselves be submitted to selection, and certain of these will be in their turn eliminated. In this way a group of organisms becomes more and more closely adapted to its surroundings; and unless new variations make their appearance as the old unfavourable ones are eliminated, the variability of the species will diminish as the result of selection. Is it likely that new variations will appear in the manner suggested? To answer this question we must turn to the results obtained by human agency in the selective breeding of animals. The experience of breeders is that continued selection tends to produce a greater and greater purity of stock, characterised by small variability, so that if the selective breeding is carried too far, variation almost entirely ceases, and there is little opportunity left for the exercise of the breeder's art. When this condition has been arrived at, he is obliged, if he wants to produce any further modifications of his animals, to introduce new blood—*i.e.* to bring in an individual which has either been bred to a different standard, or one in which the variability has not been so completely extinguished.

It would thus appear, and I think we are justified in holding this view, at any rate provisionally, that the result of continued selection will be to diminish the variability of a species; and if carried far enough, to produce a race with so little variability, and so closely adapted to its surroundings, that the

slightest alteration in the conditions of life will cause extinction.[1]

If selection tends to diminish the variability of a species, then it clearly follows that as selection has been by hypothesis the most important means of modifying organisms, variation must have been much greater in past times than it is now. In fact, it must have been progressively greater the farther we go back from the present time.

The argument which I have just laid before you points, if carried to its logical conclusion—and I see no reason why it should not be so carried—to the view that at the first origin of life upon the earth the variability of living matter consequent upon the act of conjugation must have been of enormous range: in other words, it points to the view that heredity was a much less important phenomenon than it is at present. Following out the same train of thought, we are inevitably driven to the conclusion that one of the most important results of the evolutionary change has been the gradual increase and perfection of heredity as a function of organisms and a gradual elimination of variability.

This view, if it can be established, is of the utmost importance to our theoretical conception of evolution, because it enables us to bring our requirements as to time within the limits granted by the physicists. If variation was markedly greater in the early periods of the existence of living matter, it is clear that it would have been possible for evolutionary change to have been effected much more rapidly than at present—especially when we remember that the world was then comparatively unoccupied by organisms, and that with the change of conditions consequent on the cooling and differentiation of the earth's surface, new places suitable for organic life were continually being formed. It will be observed that the conclusion we have now reached, viz. that variation was much greater near the dawn of life than it is now, and heredity a correspondingly less important phenomenon, is a deduction from the selection theory. It becomes, therefore, of some interest to inquire whether a suggestion obtained by a perfectly legitimate mode of reasoning receives any independent confirmation from other sources. The first source of facts to which we turn for such confirmation must obviously be palæontology. But palæontology unfortunately affords us no help. The facts of this science are too meagre to be of any use. Indeed, they are wanting altogether for the period which most immediately concerns us—namely, the period when the existing forms of life were established. This took place in the prefossiliferous period, for in the earliest fossiliferous rocks examples of almost all existing groups of animals are met with.

But although palæontology affords us no assistance, there is one class of facts which, when closely scrutinised, do lend some countenance to the view that when evolutionary change was at its greatest activity, *i.e.* when the existing forms of life were being established, variation was considerably greater than it is at the present day.

But as this address has already exceeded all reasonable limits, and as the question which we are now approaching is one of very great complexity and difficulty, I am reluctantly compelled to defer the full consideration and treatment of it to another occasion. I can only hope that the far-reaching importance of my subject and the interest of it may to some extent atone for the great length which this address has attained.

### APPENDIX.

The following observations on the condition of the male reproductive organs in highly variable plants are quoted from Darwin's "Variation of Animals and Plants under Domestication," vol. ii. p. 256 *et seq.*

In certain plant hybrids which are highly variable, it is known that the anthers contain many irregular pollen-grains. Exactly the same fact has been noticed by Max Wichura in many of our highly cultivated plants which are extremely variable, and which there is no reason to believe have been hybridised, such as the hyacinth, tulip, snapdragon, potato, cauliflower, &c.

[1] The expression extinction of species seems to be used in two senses which are generally confused. Firstly, a species may become modified so that the form with which we are familiar gradually gives place to one or more forms which have been gradually produced by its modification. That is to say, a character or series of characters becomes gradually modified or lost in successive generations. This is not really extinction, but development. Secondly, a species may gradually lose its variability, and become fixed in character. If the conditions then change, it is unable to adapt itself to them, and becomes truly extinct. In this case it leaves no descendants. We have to do with death, and not with development.

The same observer also "finds in certain wild forms the same coincidence between the state of the pollen and a high degree of variability, as in many species of *Rubus*; but in *R. caesius* and *idaeus*, which are not highly variable species, the pollen is sound." A little further on Darwin says "these facts indicate that there is some relation between the state of the reproductive organs and a tendency to variability; but we must not conclude that the relation is strict." Finally he sums up the matter in these words: "On the whole it is probable that any cause affecting the organs of reproduction would likewise affect their product—that is, the offspring thus generated."

## NOTES.

IN his address to the French Association, at the recent Boulogne meeting, Dr. P. Brouardel took as his theme "Hygiene and its Progress during the last 100 Years." He paid special homage to the memory of the great Englishman and Frenchman, Jenner and Pasteur, who had done so much for the promotion of medical science. The first operation in vaccination made in France was performed at Boulogne, June 18, 1800. A public monument—a statue of Jenner—records the event. Referring to some preventive diseases, Dr. Brouardel remarked that in the French army the mortality from typhoid fever is now about 12 in 10,000, and in the present state of the water supply of many towns it is believed that this mortality will not be much reduced. In the German army, however, the mortality from typhoid fever is as low as 1 and 2 per 10,000, owing doubtless to the fact that an order of a Government authority addressed to any municipal body is immediately carried out, so that an impure water supply has soon to be replaced by a better one. But though some French municipalities are indifferent to their responsibilities, others do their duty well, and the mortality from typhoid fever for the whole of France is only 3 per 10,000. Dr. Brouardel referred to several other subjects which came within the range of preventive medicine.

THE application of the Jenner Institute of Preventive Medicine for permission to alter the memorandum of association so as to enable the institute to avail itself of Lord Iveagh's gift of 250,000*l.* was granted by Mr. Justice Cozens Hardy on September 13.

AFTER four months' work on his yacht, Dr. H. C. Sorby, F.R.S., has returned to Sheffield with many hundred specimens of marine animals, preserved by his new methods, so as to show lifelike character and natural colour.

THE Director of the Marine Observatory of San Fernando announces that the Spanish Minister of Finance has given instructions that all instruments intended for observations of the eclipse of the sun on May 27, 1900, are to be admitted free of duty.

SIR WILLIAM PREECE, K.C.B., has recently been making experiments with an electromagnetic system of wireless telegraphy in the Menai Straits. Using a telephone as a receiver, he has succeeded in establishing communication between stations half a mile apart, the messages heard being signals on the Morse code.

WE learn from the *Scientific American* that Prof. J. B. Hatcher, of Princeton University, has just returned from his geological expedition to Patagonia. The primary object of Prof. Hatcher's expedition was to make the most extensive collections possible of fossils of Patagonia. He also devoted considerable attention to gathering ethnological, botanical and zoological specimens. The first Mesozoic mammals ever discovered were found in Patagonia on this expedition, and upward of thirty cases of Mesozoic vertebrates were shipped

north. Naturally Prof. Hatcher gathered much valuable material illustrating the life and customs of the Patagonian Indian tribes, and he has obtained an important series of photographic negatives which depict the geological and physiographic features of that region.

THE *British Central Africa Gazette* (July 24), published at Zomba, announces the arrival at Nyasa of Mr. J. E. S. Moore, who visited Lakes Shirwa, Nyasa, and Tanganyika in 1896 under the auspices of the Royal Society, and has again returned to Central Africa to survey the basin of Lake Tanganyika, to collect specimens of the aquatic fauna and flora, and to study the geological history of this portion of the great Central African rift. Mr. Moore has with him a complete set of apparatus for deep-water dredging, and the results of the present expedition should be even more satisfactory and interesting than those of the previous investigation. On the way to Tanganyika, deep sounding and dredging operations will be made in Lake Nyasa, the Administration gunboat *Guendolen* having been placed at the disposal of the expedition for this purpose. It is intended to spend several months on Lake Tanganyika, and, after leaving the north end of that lake, to proceed to Lakes Kivu, Albert Edward, and Albert, whence it is proposed to make for the East African coast.

WE regret to see the announcement of the death of M. Gaston Tissandier, the founder of our Parisian namesake, *La Nature*, and the author of a number of scientific works. For many years M. Tissandier devoted much attention to ballooning, and made many balloon ascents, during which he obtained information of value to aëronautics and meteorology. The results of his investigations will be found in the *Comptes rendus* of the Paris Academy of Sciences. He was nominated president of the French Association of aërial navigation, and in 1876 received from the Association the Janssen gold medal. His first memoir on the application of electricity to aërial navigation was crowned by the Paris Academy of Sciences. In 1886, M. Tissandier was made a member of the committee on aëronautics by the Minister of War, and also of the civil committee on the same subject by the Minister of the Interior. He was a member of many scientific societies in France, and a vice-president of the French Meteorological Society. He was made a Chevalier of the Legion of Honour in 1872, and in 1893 the Society for the Encouragement of National Industry awarded him the grand gold medal. In addition to his scientific papers, M. Tissandier was the author of several volumes on physics, chemistry, photography, and ballooning.

MR. C. E. STROMEYER has sent us a stereoscopic photograph of what appears to him to have been an induced lightning flash, taken by Mr. S. Jewsbury at Didsbury. The camera by which the photograph was obtained was placed upon the sill of an open window during a thunderstorm, in order to depict any flashes of lightning which might come within its field of view. No flashes were seen in this part of the sky, but when the plate was developed a broken streak of light appeared upon the two pictures. The trail is horizontal and directed towards a lamp-post in a neighbouring road. As similar markings are often found on plates when lighted lamps are in the field, their electrical origin in the present case is difficult to establish; for they may have been produced while the camera was being placed in position, or taken away, with the lens off. Nevertheless the photograph furnishes interesting material for speculation.

MR. T. KINGSMILL sends us two cuttings from the *Shanghai Mercury* referring to two electric displays of an unusual character observed at Shanghai on July 19 and August 10. On the former occasion it is stated:—"The northern sky was in an almost constant blaze of light. Flashes came sometimes from two centres, as though there were an elliptical area of disturbance from whose foci were sent forth the shafts of lightning. At times these flashes would take the opposite course, and starting from the circumference make their way to the foci. Though the lightning flashes reached within twenty-five degrees of the zenith, and were vigorous enough in all conscience, yet nothing but the faintest distant rumbling could be heard." On August 10 "the reflection of lightning was seen from the S.W. and gradually increased in brightness until at about 7.50 it had reached the zenith." The report states that "the lightning played over nearly the whole of the exposed sky, sometimes six and seven streamers at a time lighting up the sky. They were different in appearance from ordinary forked lightning, having rather the appearance of a network of ribbons crossing the exposed sky in all directions, like the discharges in a vacuum tube. The most unusual circumstance was that these discharges, though most vivid, were almost noiseless, and could scarcely be heard above the ordinary jinrickshaw traffic of the street, the only accompanying sound to the brightest display even in the zenith being a low rumbling, as of ordinary very distant thunder." Mr. Kingsmill remarks that both displays were synchronous with distant typhoons.

AT a meeting of the Lincolnshire Naturalists' Union and the Lincolnshire Science Society, on September 11, Dr. G. M. Lowe, the president of both Societies, expressed the hope that something would soon be done to give science—both natural and physical—in Lincolnshire, first, a permanent home, secondly, the means of making useful observations, and thirdly, of recording them. The first requires the establishment of a museum, which would at once be a memorial of the great men who had been born and lived in Lincolnshire, amongst whom may be mentioned Isaac Newton, Sir John Franklin, and Mr. John Cordeaux. As a repository of specimens of the fast disappearing fauna and flora of our former fen country, of specimens of local antiquarian interest, of specimens bearing on the technique of our local arts and manufactures, a museum worthy of Lincolnshire would soon become invaluable. Next month the county authorities will consider an application for space within the Old Keep of the Castle, to erect buildings for an observatory for the reception of astronomical instruments offered to the county, and for a meteorological station. A third requirement is a means of recording and preserving the observations and papers of members of the scientific societies in the county. A magazine devoted to natural and physical science could, Dr. Lowe felt sure, be supported by Lincolnshire alone; and if the writers of observations and of papers on scientific subjects could be persuaded to drop the pedantic, and use as far as possible a simple phraseology, a highly interesting and useful publication could be provided, which would have a stimulating effect in directing the scientific education of the younger generation.

WE have received from Prof. A. Klossovsky a copy of a paper read before the congress of naturalists, &c., at Kieff, entitled, "The Physical Life of our Planet." The author treats the subject on the supposition that the earth is similar to a living organism, in which the various functions and elements are closely connected according to certain laws. He considers that even the variations of terrestrial magnetism depend upon a system of currents which traverse the atmosphere and are in evident correlation with the cyclonic activity of the air, and, further, that the magnetic and electric fields have an influence on the progress of phenomena at the surface of the earth. He gives some interesting accounts of the most recent acquisitions of science in the determination of the different forces which constitute the physics of the globe.

THE U.S. Hydrographic Office has received a sufficient number of reports to enable it to lay down, with substantial accuracy, the track of the destructive West India hurricane referred to in our issue of August 17 (p. 374). It appears to have been first encountered on August 3, in lat. 11° 51′ N., long. 35° 42′ W., further east than any tropical storm hitherto reported to that Office. At noon (Greenwich time) on the 7th, observations of barometers and winds between St. Kitts and Barbados showed unmistakably the presence of a hurricane to the eastward. The centre of the storm reached Porto Rico on the 8th, Haiti on the 9th, Bahamas on the 12th, and Jupiter, on the Florida coast, on the 13th, and then continued its path parallel to the general trend of the U.S. coast, where vessels continued to report gales of hurricane force until the 19th. The lowest barometer reading, 28·35 inches, appears to have occurred off the Florida coast on August 14. When the hurricane was last reported, in the afternoon of the 21st, it was near lat. 40° N. and long. 60° W., much weakened in energy. The life of the storm is longer than any hitherto reported to the Hydrographic Office.

THE thirty-sixth annual report of the Government Cinchona Plantation in Sikkim, by Surgeon-Major D. Prain, shows that the issues of quinine during the year 1897–98 amounted to 10,939 lbs., as against 8482 lbs. in 1896–97. The medical depôts required 1710 lbs. more than during the preceding year, and the sales to Government officers for distribution in their districts exceeded those of 1896–97 by 1086 lbs. As Sir George King feared, there has been a very marked decline in the demand for quinine for division into pice-packets for sale at Post-offices. The falling off in the demand, so far as Bengal is concerned, may be due to some special cause not active elsewhere; at all events, 800 lbs. have been asked for and supplied during the year for conversion into pice-packets in the North-western Provinces.

DURING the year 1898–99 covered by the report of the Royal Botanic Garden, Calcutta, especial attention was given to the cultivation and distribution of plants of economic value. In connection with the question of rubber and gutta-percha, it has been ascertained, after examination of the milky juice of species of Sideroxylon belonging to the natural family Sapotaceæ, that, though these species do not yield a true rubber, the material obtained from them might prove capable of being utilised for the various purposes for which gutta-percha or india-rubber is now employed. An interesting introduction to India during the year was *Polygala butyracea*, an African species, which yields an excellent vegetable oil. The cultivation and the identification of living plants yielding Indian products of hitherto doubtful origin were continued during the year with good results.

WE have received two papers on earthquakes registered at the observatory of Catania during the present year (*Boll. dell' Accad. Gioenia di Sci. Nat. in Catania*, 1899). Prof. Riccò describes the records of an earthquake in the Peloponnesus on January 22 made by the great seismometrograph, which is 25·3 m. long and has a mass of 300 kg., and by the Brassart seismometrograph. Mr. Arcidiacono gives an account of three diagrams obtained by the former instrument between 7 and 10 p.m. (G.M.T.) on May 3, the first being evidently made by a distant earthquake, which proved to be a strong shock in the Peloponnesus; and the other two by local shocks originating below the south-west flank of Etna at the same spot as the destructive earthquake of May 14, 1898. The author suggests that the Sicilian focus was in a critical condition, and that the two movements there were precipitated by the earlier disturbance in Greece.

THE Free Museum of Science and Art of the University of Pennsylvania issues an illustrated *Bulletin*, in the last number of which (vol. ii. No. 2) an account is given of the new museum buildings in which will be lodged the fine collections of Drs. W. H. Furness and H. M. Hiller and Mr. A. C. Harrison, jun., from Borneo and adjacent islands; the collection from Sarawak is second only to that in the Sarawak Museum at Kuching, and in some respects probably surpasses it. The *Bulletin* contains a report on the recent excavations of the University at Nippur, an account of the Rittenhouse Orrery, and a catalogue of the recent additions to the Museum, some of the more interesting specimens being figured.

THE Dorset County Council has set a good example in arranging for a series of reports with analyses of the soils of the county. The work has been carried out in Reading College under the superintendence of Mr. Douglas A. Gilchrist, and the soils have been analysed by Mr. C. M. Luxmoore and Mr. A. M. Ryley. The first annual report has just reached us; it forms Supplement No. viii. to the *Journal* of Reading College, August 1899. Soils have been taken from areas where different geological formations are developed from the Lower Lias of the Vale of Marshwood to the Reading Beds near Wimborne; a few analyses are also given of soils from Berkshire, Hampshire, and Oxfordshire. The results so far obtained are full of interest, and are likely to prove of great practical importance. Suggestions are made for the manuring of the principal farm crops on the different classes of soils, as well as on the suitability of the soils for particular crops.

AN excellent "Sketch of the Geology of the Lower Carboniferous Rocks of Derbyshire" has been contributed by Mr. H. H. Arnold Bemrose to the August number of the *Proceedings* of the Geologists' Association. The Mountain Limestone with its caverns and lead mines, the Yoredale Rocks and the Millstone Grit are duly described, and the leading fossils are noted. Mention is made of Dr. Wheelton Hind's opinion that the Yoredale Rocks of Derbyshire are newer than those of the typical district in Wensleydale. Further research on this subject is needed. References are made to the Glacial Drift, the Pleistocene Mammalia, the Warm Springs, and other subjects. A more particular account is given of the igneous rocks generally known as Toadstones, and of the occurrence of volcanic vents, as well as tuffs, lavas and sills. There are notes also on marmorised, dolomitised and silicified limestones. The article is well illustrated with maps, sections, and pictorial views.

MANY persons are under the impression that shore-nesting birds make no nest, but lay their eggs indiscriminately among the shingle. This Mr. Patten, in the September number of the *Irish Naturalist*, shows to be a complete misconception so far as the Little Tern is concerned. As a matter of fact, the bird excavates a conical pit in the sand about two inches deep. Immediately round the "crater" a narrow zone of sand is cleared from shingle; and when completed and containing its full clutch of two or three eggs, the deepest part of the nest is filled with broken shells, into which the eggs are wedged with their points downwards. As the eggs are disproportionately large in relation to the bird, it is manifest that the position in which they are placed renders them most easily covered by the brooding hen. It has been assumed that the "crater" is excavated by the hen-bird "breasting" the sand in the manner that sparrows dust themselves by the road-side, but the author is of opinion that the work is done with the beak.

THE discussion in regard to the Ground-sloth whose skin and other remains have been found in a cave in Patagonia has assumed a new phase. It will be remembered that in a recent

contribution to our columns Dr. Moreno stated his belief that the animal belonged to the genus *Glossotherium* (= *Grypotherium*), the creation of a new genus (*Neomylodon*) for its reception being accordingly superfluous. Accepting this determination, but using the synonym *Grypotherium*, Dr. R. Hauthal, in a paper recently communicated to the "Revista del Museo de la Plata" (vol. ix. p. 409), comes to the conclusion that the animal in question was kept by the prehistoric Indians of Patagonia in a domesticated state, and that the cave at Ultima Esperanza was the stable where the herd was nightly collected! Several specimens of the hide, as well as abundant droppings in a dried state, have been obtained; but in spite of this, the author is of opinion that all the remains date from prehistoric times. And he gives reasons for the belief that the creature cannot be living at the present day. Considering the animal in question to be distinct from the typical species, the author and his colleague Mr. Roth bestow the new title *G. domesticum*, apparently oblivious of Dr. Ameghino's earlier name *listai*. The promised continuation of this remarkable paper will be awaited with interest.

SOME very interesting features in development are brought to light in Mr. J. S. Budgett's "Notes on Batrachians of the Paraguayan Chaco," published in the last issue of the *Quarterly Journal of Microscopical Science*. It is well known that in some of the arboreal frogs the tadpole stage, to meet the necessities of existence, is more or less abbreviated; and the author describes an instance of this in a species of *Phyllomedusa*, illustrating his notes with a beautiful coloured plate. After mentioning how the male and female hold together the edges of a leaf (which afterwards become united by the jelly of the egg-mass) during oviposition so as to form a funnel for the reception of the eggs, the developmental stages are described in detail. In the short period of six days the embryo leaves the egg as a pellucid tadpole of a bright green colour, whose only conspicuous parts are its eyes. The tadpole, which may have to travel several inches in order to reach the water, is hatched without a trace of yolk, and with the loss of external gills; breathing taking place by means of a median spiracle, and the lungs being distinctly visible through the body-wall. Pigment is locally developed next day; and at the end of about five weeks the hind limbs appear. When both pairs of limbs are developed, the young frog lands, and sits quietly among the grass till its tail is completely absorbed, when it is practically adult.

THE second volume of Prof. G. O. Sars' work on the Crustacea of Norway, dealing with the Isopoda, has just been completed. The volume is the first in which the Scandinavian Isopoda are treated as a whole, and it should be of much practical use to zoologists. The third volume of the work, now in preparation, will treat of the anomalous group Cumacea, and will consist of about 150 pages with sixty plates.

AT the Royal Victoria Hall, Waterloo Bridge Road, the following popular science lectures will be delivered on Tuesday evenings during October:—October 3, "The Value of Nitrogen," Prof. Holland Crompton, F.R.S. October 10, "Liquid Air," Prof. W. Ramsay, F.R.S. October 17, "Source and Course of the River Thames," Dr. C. G. Cullis. October 24, "Photographs taken in the Dark," Dr. Russell, F.R.S. October 31, "Kamchatka," Captain Barrett Hamilton.

THE additions to the Zoological Society's Gardens during the past week include a Maholi Galago (*Galago maholi*) from South Africa, presented by Mr. James W. Park; two Black-eared Marmosets (*Hapale penicillata*) from South-east Brazil, presented by Mr. F. M. Still; a Guinea Baboon (*Cynocephalus sphinx*, ♀) from West Africa, presented by Mr. J. Huxley; a Black-backed Jackal (*Canis mesomelas*), four Bristly Ground Squirrels (*Xerus setosus*), a Vulturine Eagle (*Aquila verreauxi*, juv.), two Hispid Lizards (*Agama hispida*), four Delalande's Lizards (*Nucras delalandii*), seven Rufescent Snakes (*Leptodira hotambaeia*), four Crossed Snakes (*Psammophis crucifer*), five Rhomb-marked Snakes (*Trimerorhinus rhombeatus*), eight Rough-keeled Snakes (*Dasypeltis scabra*), an Infernal Snake (*Boodon infernalis*), two Puff Adders (*Bitis arietans*) from South Africa, presented by Mr. J. E. Matcham; a Fulmar (*Fulmarus glacialis*) from Iceland, presented by Mr. G. S. Hett; a Lapwing (*Vanellus cristatus*), British, presented by the Rev. A. Barham Hutton; a Herring Gull (*Larus argentatus*), British, presented by Mr. J. L. Bell; two Common Chameleons *Chamaeleon vulgaris*) from North Africa, presented by Mr. Ronald H. Archer; a Common Viper (*Vipera berus*), British, presented by Mr. P. Debell Tuckett; a Kinkajou (*Cercoleptes caudivolvulus*) from South America, an Arctic Fox (*Canis lagopus*) from Finland, a Palm Squirrel (*Sciurus palmarum*, albino) from India, a Black-headed Conure (*Conurus nanday*) from Paraguay, deposited.

NEW SPECTROSCOPIC MULTIPLE STAR.—The San Francisco correspondent of the *Standard* (September 11) reports that Prof. W. W. Campbell, of the Lick Observatory, announces that he has obtained spectroscopic evidence that the North Pole star, Polaris, is in reality a system consisting of three bodies. Two of these revolve round each other in a period of *four* days, and simultaneously they together revolve around a third body, in the same manner as the earth and planets revolve round the sun. It is improbable that any of these distant bodies will ever be visible separately, their distance from each other being so small that it can only be detected by the change in wave-length of the lines in the spectrum of the system, owing to the continual approach and recession of each component during their mutual revolutions.

SOUTHERN VARIABLE STARS.—In the *Astronomical Journal* (No. 468), Mr. R. T. A. Innes gives the results of observations on variable stars made at the Cape Observatory since 1896. The working catalogue was mainly derived from lists supplied by Prof. J. C. Kapteyn, who noted all suspected cases of variability in the course of his work on the *Cape Photographic Durchmusterung*. The present communication considers twenty-seven stars, of which one is probably of the Algol type. The period of this is found to be 12·906 days, and consequently this star is conspicuous as being the longest period Algol variable. Its position is

$$\left.\begin{array}{l}\text{R.A. 7h. 42m. 41·1s.}\\ \text{Decl.} - 41^\circ\ 4'\cdot 0\end{array}\right\}(1875);$$

The visual variation of magnitude is from 9·5 to 10·7, and photographically from 9·3 to 10·2.

THE *Bulletin de la Société Astr. de France* for September contains several interesting papers.—"Photography of stellar spectra," by Prof. A. Cornu, consists of a short description of the methods and results of researches into stellar constitution. MM. Flammarion and Antoniadi describe their most recent observations of Mars, including illustrations showing the land-

markings and the variations of the polar cap with the seasons.—M. Em. Touchet contributes an illustrated account of his successful attempt to photograph the "shadow cast by the planet Venus." This he did on January 11, with an exposure of fifteen minutes, the object casting the shadow being an incandescent bulb-holder placed about 21 cm. from the plate.—Lastly, rather more than nine pages are devoted to a dissertation, by M. Rideau, on "the satellites of Jupiter," dealing with their dimensions, surface, probable variability of brightness, eclipse and other phenomena.

## *SOLID HYDROGEN.*[1]

IN the autumn of 1898, after the production of liquid hydrogen was possible on a scale of one or two hundred c.c., its solidification was attempted under reduced pressure. At this time, to make the isolation of the hydrogen as effective as possible, the hydrogen was placed in a small vacuum test-tube, placed in a larger vessel of the same kind. Excess of the hydrogen partly filled the circular space between the two vacuum vessels. The apparatus is shown in Fig 1. In this way the evaporation was mainly thrown on the liquid hydrogen in the annular space between the tubes. In this arrangement the outside surface of the smaller tube was kept at the same temperature as the inside, so that the liquid hydrogen for the time was effectually guarded from influx of heat. With such a combination the liquid hydrogen was evaporated under some 10 mm. pressure, yet no solidification took place. Seeing experiments of this kind required a large supply of the liquid, other problems were attacked, and any attempts in the direction

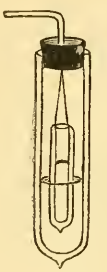

FIG 1.

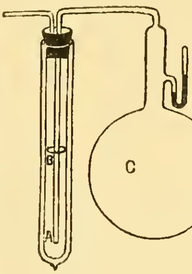

FIG 2.

of producing the solid for the time abandoned. During the course of the present year many varieties of electric resistance thermometers have been under observation, and with some of these the reduction of temperature brought about by exhaustion was investigated. Thermometers constructed of platinum and platinum-rhodium (alloy) were only lowered $1\frac{1}{2}°$ C. by exhaustion of the liquid hydrogen, and they all gave a boiling point of $-245°$ C., whereas the reduction in temperature by evaporation *in vacuo* ought to be $5°$ C., and the true boiling point from $-252°$ to $-253°$ C. In the course of these experiments it was noted that almost invariably there was a slight leak of air, which became apparent by its being frozen into an air snow in the interior of the vessel, where it met the cold vapour of hydrogen coming off. When conducting wires covered with silk have to pass through india-rubber corks it is very difficult at these excessively low temperatures to prevent leaks, when corks get as hard as a stone, and cements crack in all directions. The effect of this slight air leak on the liquid hydrogen when the pressure got reduced below 60 mm. was very remarkable, as it suddenly solidified into a white froth-like mass like frozen foam. My first impressions were that this body was a sponge of solid air containing the liquid hydrogen, just like ordinary air, which is a magma of solid nitrogen containing liquid oxygen. The fact, however, that this white solid froth evaporated completely at the low pressure without leaving any substantial amount of solid air led to the conclusion that the body after all must be solid hydrogen. This surmise was confirmed by observing that if the pressure, and therefore the temperature, of the hydrogen was allowed to rise, the solid melted when the pressure reached about 55 mm. The failure of the early experiment must then have been due to supercooling of the liquid, which is prevented in this case by contact with metallic wires and traces of solid air. To settle the matter definitely, the following experiment was arranged. A flask, C, of about a litre capacity, to which a long glass tube bent twice at right angles was sealed, as shown in Fig. 2, and to which a small mercury manometer can be sealed, was filled with pure dry hydrogen and sealed off. The lower portion, A B, of this tube was calibrated. It was surrounded with liquid hydrogen placed in a vacuum vessel arranged for exhaustion. As soon as the pressure got well reduced below that of the atmosphere, perfectly clear liquid hydrogen began to collect in the tube A B, and could be observed accumulating until, about 30 to 40 mm. pressure, the liquid hydrogen surrounding the outside of the tube suddenly passed into a solid white foam-like mass, almost filling the whole space. As it was not possible to see the condition of the hydrogen in the interior of the tube A B when it was covered with a large quantity of this solid, the whole apparatus was turned upside down in order to see whether any liquid would run down A B into the flask C. Liquid did not flow down the tube, so the liquid hydrogen with which the tube was partly filled must have solidified. By placing a strong light on the side of the vacuum test-tube opposite the eye, and maintaining the exhaustion to about 25 mm., gradually the solid became less opaque, and the material in A B was seen to be a transparent ice in the lower part, but the surface looked frothy. This fact prevented the solid density from being determined, but the maximum fluid density has been approximately ascertained. This was found to be 0·086, the liquid at its boiling point having the density 0·07. The solid hydrogen melts when the pressure of the saturated vapour reaches about 55 mm. In order to determine the temperature, two constant volume hydrogen thermometers were used. One at $0°$ C. contained hydrogen under a pressure of 269·8 mm., and the other under a pressure of 127 mm. The mean temperature of the solid was found to be $16°$ absolute under a pressure of 35 mm. All the attempts made to get an accurate electric resistance thermometer for such low temperature observations have been so far unsatisfactory. Now that pure helium is definitely proved to be more volatile than hydrogen, this body, after passing through a spiral glass tube immersed in liquid hydrogen to separate all other gases, must be compared with the hydrogen thermometer. For the present the boiling point which is $21°$ absolute at 760 mm., compared with the boiling point at 35 mm., or $16°$ absolute, enables the following approximate formula for the vapour tension of liquid hydrogen below one atmosphere pressure to be derived :—

$$\log p - 6{\cdot}7341 - 83{\cdot}28/T \text{ mm.},$$

where $T$ = absolute temperature, and the pressure is in mm. This formula gives us for 55 mm. a temperature of $16{\cdot}7°$ absolute. The melting point of hydrogen must therefore be about $16°$ or $17°$ absolute. It has to be noted that the pressure in the constant volume hydrogen thermometer, used to determine the temperature of solid hydrogen boiling under 35 mm., had been so far reduced that the measurements were made under from one-half to one-fourth the saturation pressure for the temperature. When the same thermometers were used to determine the boiling point of hydrogen at atmospheric pressure, the internal gas pressure was only reduced to one-thirteenth the saturation pressure for the temperatures. The absolute accuracy of the boiling points under diminished pressure must be examined in some future paper. The practical limit of temperature we can command by the evaporation of solid hydrogen is from $14°$ to $15°$ absolute. In passing it may be noted that the critical temperature of hydrogen being $30°$ to $32°$ absolute, the melting point is about half the critical temperature. The melting point of nitrogen is also about half its critical temperature. The foam-like appearance of the solid when produced in an ordinary vacuum is due to the small density of the liquid, and the fact that rapid ebullition is substantially taking place in the whole mass of liquid. The last doubt as to the possibility of solid hydrogen having a metallic character has been removed, and for the future hydrogen must be classed among the non-metallic elements.

[1] Read before the British Association (Section B), Dover Meeting, by Prof. James Dewar, F.R.S.

## AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

AS already notified, the forty-eighth meeting of the American Association for the Advancement of Science was held at Columbus, Ohio, on August 19–26. Dr. W. O. Thompson, President of the Ohio State University, welcomed the Association on behalf of the University, and Dr. Edward Orton, the President, in expressing the thanks of the Association, briefly referred to some of the scientific advances of the present century.

The address of Prof. F. W. Putnam, the retiring President of the Association, was printed in NATURE of September 7, and the following are extracts from some of the addresses delivered by the Presidents of the Sections.

### THE FUNDAMENTAL PRINCIPLES OF ALGEBRA.

In his address to the Section of Mathematics and Astronomy, Prof. Alexander Macfarlane reviewed historically and critically the several advances which have been made in the present century respecting the fundamental principles of algebra. The conclusion reached, after a statement and criticism of algebraic symbols, operations and laws, is as follows:—

If the elements of a sum or a product are independent of order, then the written order of the terms is indifferent, and the product of two such sums is the sum of the partial products; but when the elements of a sum or of a product have a real order, then the written order of the elements must be preserved, though the manner of their association may be indifferent, and a power of a binomial is then different from a product. This applies whether the sum or product occurs simply, or as the index of a base.

Descartes wedded algebra to geometry; formalism tends to divorce them. The progress of mathematics within the century has been from formalism towards realism; and in the coming century, it may be predicted, symbolism will more and more give place to notation, conventions to principles, and loose extensions to rigorous generalisations.

### THE FIELD OF EXPERIMENTAL RESEARCH.

Prof. Elihu Thomson described to the Section of Physics a few of the recent developments of physical science, and pointed out that physical research by experimental methods is both a broadening and a narrowing field. There are many gaps yet to be filled, data to be accumulated, measurements to be made with great precision, but the limits within which experimental work can be done are becoming, at the same time, more and more defined. In most fields of research progress in the future will depend in an increasing degree upon the possession, by the investigator, of an appreciation of small details and magnitudes, together with a refined skill in manipulation or construction of apparatus. He must be ready to guide the trained mechanic, and be able himself to administer those finishing touches which often mark the difference between success and failure.

In conclusion, Prof. Thomson remarked that his endeavours had been to indicate in his address directions in which the field of experiment may be extended, and to emphasise the fact that research must be carried on by extension of limits, necessitating more liberal endowment of research laboratories. The physicist must avail himself of the powers and energies set in play in the larger industrial enterprises, and finally the field of possible exploration in physics by experimental methods has its natural boundaries, outside of which our advances in knowledge must be derived from a study of celestial bodies.

The riddle of gravitation is yet to be solved. This all-permeating force must be connected with other forces and other properties of matter. It will be a delicate task, indeed, for the total attraction between very large masses closely adjacent, aside from the earth's attraction, is very small.

Scientific facts are of little value in themselves. Their significance is their bearing upon other facts, enabling us to generalise and so to discover principles, just as the accurate measurement of the position of a star may be without value in itself, but in relation to other similar measurements of other stars may become the means of discovering their proper motions. We refine our instruments; we render more trustworthy our means of observation; we extend our range of experimental inquiry, and thus lay the foundation for the future work, with the full knowledge that, although our researches cannot extend beyond certain limits, the field itself is, even within those limits, inexhaustible.

### THE DEFINITION OF THE ELEMENT.

Prof. F. P. Venable briefly discussed the nature of the elements in his address to the Section of Chemistry. He passed in review some of the evidence which leads to the belief that the so-called elementary atoms are but compounds of an intimate peculiar nature, the dissociation of which has not yet been accomplished. Referring to the conclusions to which investigations lead, it was remarked that the hypothesis that the elements are built up of two or more common constituents has a larger number of supporters, and would seem more plausible than Graham's hypothesis. Some have supposed one such primal element by the condensation or polymerisation of which the others were formed. Others have adopted the supposition of two elements.

There are many practical difficulties in the way of these suppositions; the lack of uniformity in the differences between the atomic weights, the sudden change of electro-chemical character, and the impossibility, so far, of discovering any law underlying the gradation in the properties of the elements with the increase of atomic weights, are some of the difficulties. In comparing these two hypotheses, that of Graham seems very improbable. It is possible to think of valency as dependent upon the character of the motion of the atom, but one cannot well conceive of a similar dependence of atomic weight and all the other properties. There remains, then, the hypothesis of primal elements by the combination of which our elements have been formed. These molecules are probably distinguished from the ordinary molecules by the actual contact and absolute union of the component atoms without the intervention of ether.

Since these elemental molecules cannot as yet be divided, the name atom may be retained for them, but the idea of simplicity and homogeneity no longer belongs to them. The definition of an element as a body made up of similar atoms is equally lacking in fidelity to latest thought and belief, but chemists would scarcely consent to change it, and, indeed, it may well be retained, provided the modified meaning is given to the word atom. But, after all, an element is best defined by means of its properties. It is by close study of these that its elemental nature is decided, and through them it is tested. Complete reliance can no longer be placed upon the balance and the supposed atomic weight.

### THE DEVONIAN SYSTEM OF CANADA.

Mr. J. F. Whiteaves's address to the Section of Geology and Geography was upon the present state of knowledge of the Devonian rocks of Canada, from a palæontologist's point of view. In accordance with long usage in Canada, the line of demarcation between the Silurian and Devonian systems was drawn at the base of the Oriskany sandstone. The information that has so far been gained about the Devonian rocks of Canada was considered in geographical order, from east to west, under the three following heads, viz. (1) The Maritime Provinces and Quebec; (2) Ontario and Keewatin; and (3) Manitoba and the North-west Territories.

The present state of our knowledge of the Devonian rocks of the whole Dominion, from a purely palæontological standpoint, was thus briefly summarised:—We now possess a fairly satisfactory knowledge of the fossils of the Devonian rocks of Ontario, and of the relations which these rocks bear to the typical section in the State of New York. The fossil plants of the Gaspé sandstones have been described and figured by Sir William Dawson, and the remarkable assemblages of fossil fishes from the Upper Devonian of Scaumenac Bay and Lower Devonian near Campbellton have been worked out somewhat exhaustively, the earlier collections in Canada, and the later ones by the best ichthyological authorities in London and Edinburgh. We have now some idea of the fossil fauna of the Manitoba Devonian, and have added materially to our knowledge of the fossils of the Devonian rocks of the Athabasca and Mackenzie River districts. But, on the other hand, our knowledge of the organic remains of the Devonian of Nova Scotia is still in its infancy, and it would seem that the plant-bearing beds near St. John, N.B., which have so long been regarded as Devonian, may possibly be Carboniferous. In the Rocky Mountain region of Alberta we have not always succeeded in distinguishing Devonian rocks from Carboniferous, and we have yet to obtain a much fuller knowledge than we now possess of the Devonian fossils of Keewatin and the area to the south-west of James Bay.

ENGINEERING EDUCATION.

The address of Prof. Storm Bull, before the Section of Mechanical Science and Engineering, was on engineering education as a preliminary training for scientific research work. The proposition put forward was that engineering education as furnished in the best technical schools of the world, together with the training obtained later in life as a practising engineer, provides the best preliminary preparation for the successful prosecution of scientific research work.

## *UNIVERSITY AND EDUCATIONAL INTELLIGENCE.*

MR. A. G. ASHCROFT has been appointed Assistant Professor of Engineering at the Central College of the City and Guilds of London Institute.

DURING the winter session 1899-1900 at the University of Edinburgh, courses on practical experimental physiology, practical chemical physiology, and practical histology, will be given every week day, in addition to the usual five months' course on physiology.

AMONG the addresses to be delivered at the opening of the Medical Schools in the beginning of October are the following:—At the Middlesex Hospital the introductory address will be delivered by Mr. John Murray. At St. George's Hospital the introductory address will be given by Dr. Howship Dickinson. At University College the session will be opened by Dr. G. F. Blacker. At St. Mary's Hospital the address will be given by Mr. H. G. Plimmer. At Charing Cross Hospital the address will be delivered by Dr. Mitchell Bruce. At Guy's the term begins on October 2, when the first meeting of the session of the Physical Society will be held at 8, in the new physiological theatre. Sir Samuel Wilks will preside. At the London School of Medicine for Women the introductory address will be given by the dean, Mrs. Garrett Anderson, after which the prizes for the past year will be distributed. The winter session of the London School of Tropical Medicine will open on October 2, when the new school will be formally opened to students. At St. Thomas's Hospital the session will open on October 3, when the prizes will be distributed by Prof. Clifford Allbutt. The winter session at Mason College, Birmingham, will begin on October 2, when Sir William Gairdner will deliver the introductory address. At University College of South Wales and Monmouthshire, Cardiff, the address will be given on October 6 by Prof. A. W. Hughes. At Yorkshire College, Leeds, the address will be given on October 2, and the prizes distributed by Dr. Byrom Bramwell. The session at University College, Liverpool, will begin on October 3 with an address by the Rev. S. A. Thompson-Yates, who will afterwards distribute the prizes. The introductory lecture at Queen's College, Manchester, will be given on October 2 by Sir J. Crichton Browne.

## *SCIENTIFIC SERIAL.*

*American Journal of Science*, September.—On the gas thermometer at high temperatures, by L. Holborn and A. L. Day. The authors seek for a type of gas pyrometer yielding the most trustworthy results, and eventually decide in favour of the iridio-platinum bulb as against porcelain. They fill the bulb with nitrogen, and use a saltpetre bath up to 750°, a zinc bath up to 900°, and electric heating for still higher temperatures, since flame gases pass bodily through the metal.—On the flicker photometer, by O. N. Rood. The general idea of the photometer, which is independent of colour, is that the differently coloured beams of light traversing its axis should illuminate the two surfaces of a rectangular prism, facing the eye, and that by the oscillations of a cylindrical concave lens its illuminated surfaces should alternately and in rapid succession be presented to the eye. The resulting flicker vanishes when the two surfaces have the same luminosity.—A quantitative investigation of the coherer, by A. Trowbridge. The greater the charging potential of the coherer, the more rapid is the rise of the conductivity per unit increase in quantity of electricity discharged. Probably every coherer has a critical value of the difference of potential below which it will not act. In the ball coherer used this was 8 volts.—Double ammonium phosphates of beryllium, zinc, and cadmium in analysis, by Martha Austin. The preparation of these double ammonium phosphates is described in detail, and their utility in analytical processes is indicated.—An Albertite-like asphalt in the Choctaw Nation, Indian Territory, by J. A. Taff. The mineral, in both its physical and chemical properties, is shown to be an asphalt, and only differs from albertite in its solubility in turpentine. It occurs in veins from 4 to 25 feet thick.—A new meteorite from Murphy, Cherokee County, N.C., by H. L. Ward. The siderite described has a square fracture unusual in iron meteorites.—On the separation of alumina from molten magmas, and the formation of corundum, by J. H. Pratt. The separation of alumina is well illustrated in nature in the occurrence of corundum, spinel, and chromite in the rocks of the peridotite group. Experiments in the laboratory show that the separation of alumina as corundum from molten magmas is dependent upon the composition of the chemical compounds that are the basis of the magma, upon the oxides that are dissolved with the alumina, and upon the amount of the alumina itself. When the magma is composed of a magnesium silicate without excess of magnesia, all the alumina held by such a magma will separate out as corundum.

## *SOCIETIES AND ACADEMIES.*

PARIS.

**Academy of Sciences**, September 11.—M. Maurice Lévy in the chair.—On a new form of the equations of dynamics, by M. P. Appell. Some remarks on the new form of equation indicated in the *Comptes rendus* of August 7 and 28. The results obtained can be expressed in one theorem, with which is connected the principle of least constraint of Gauss.—The Perseids of 1899, by M. G. Flammarion. The paper gives the results of the observations of MM. Antoniadi and Mathieu at the observatory of Juvisy on August 11, 12 and 13. The results are given in tabular form, and the directions of the meteors observed are shown upon a map.—Remarks by M. Bouquet de la Grye on the above paper. It would be possible to utilise shooting stars as a means of determining differences of longitude between places unprovided with the telegraph.—On some geometrical relations between two systems of points defined by algebraic equations, by M. S. Mangeot.

## *INCANDESCENT GAS LIGHTING.*

*L'éclairage à Incandescence.* Par P. Truchot. Pp. x + 255. (Paris : Georges Carré et C. Naud, 1899.)

IN looking back to the achievements of the past half-century, few domestic improvements will strike the observer more forcibly than the advances made in the development of light from coal gas. In the early fifties the metal flat flame and argand burners were looked upon as so satisfactory and so little likely to find a rival, that practically no efforts were made to improve them, and it was only in 1852 when the late Sir Edward Frankland first made his double chimney argand—afterwards known as the Bowditch burner—in which he led the air supply down between two glass cylinders surrounding the flame, and so utilised some of the heat which would otherwise have been wasted to heat the air supplied to the flames, and found as the result a distinct increase in illuminating power, that the idea arose that it was possible to obtain more than the two to three candles of light per cubic foot of gas consumed which the best burners then gave.

Frankland's burner marks the inception of the idea of regeneration as applied to an illuminating flame, an idea perfected by Siemens in 1879 and followed by a number of regenerative burners which doubled, and in some cases nearly trebled, the light obtainable from coal gas as compared with the ordinary burner.

At the same period that the regenerative burner was struggling into prominence, Bourbouze, and later Lewis, devised a method of producing light from coal gas by burning it in a long bunsen burner, and making the flame impinge upon a mantle of fine platinum gauze, which heated to high incandescence gave more light than would have been emitted by the gas if burnt in an ordinary burner; and although this process never achieved much success owing to the fact that platinum soon got acted upon and lost its power of light emissivity, yet it was undoubtedly the forerunner of the incandescent mantle of to-day which has revolutionised our ideas as to artificial illumination, and yields ten times as much light for the same gas consumption as the ordinary No. 5 flat flame burner.

So important has incandescent lighting become, and so abundant is the literature with regard to it, that the time had clearly arrived for it to be collected and welded into a handbook that should prove a guide and companion to all working in this branch of industry. This task has been undertaken by M. Truchot, who in "L'éclairage à incandescence par le gaz et les liquides gazéifiés" has given us a concise record of the history of incandescent lighting and a work of both theoretical and practical importance.

In the twelve chapters of which the book consists, the author passes in review the properties and production of light, photometry, the proper distribution of light, the theories of Drossbach, St. John, Westphaal, Killing, Bunte and others who have attempted to explain the cause of the high incandescence of the metallic oxides forming the mantle skeleton, an excellent history of incandescent lighting and a full account of the various minerals employed as a source of the rare earths and their treatment. Especially valuable will be found the description of the various methods of making the mantle and the chief points to be observed.

The author then passes to the various forms of bunsen burner, and the results which can be obtained from them, but hardly gives sufficient credit to Bandsept's inventions, which practically cover the ground upon which the chief advances in this direction have since been made. It would have been better also if a chapter had been devoted to the theory of the bunsen burner, as it would have made the differences existing between the various forms of burner clearer.

Very excellent in its way also is the chapter devoted to the lighting of the burners, and the effect which this has upon the life of the mantle. The author also goes fairly fully into incandescent mantle lamps for use with alcohol, petroleum and other easily gasifiable hydrocarbons.

The book concludes with a review of the use of incandescent lighting for railway carriages, lighthouses, photography, &c., and comparisons of incandescent light with other systems; whilst the list of French patents for mantles and burners forms a useful finish to the work.

M. Truchot has done his work well, and his book should be in the hands of everybody interested in incandescent mantle lighting.

## *AN AMERICAN TEXT-BOOK OF GEOMETRY.*

*New Plane and Solid Geometry.* By W. W. Beman and D. E. Smith. Pp. x + 382. (Boston, U.S.A. : Ginn and Co., 1899.)

THE Americans are an eminently practical people, and in seeking for the path of least resistance towards any desired end they are happily free from the shackles of inherited prejudice and irrational reverence for established tradition. This makes their mathematical text-books very instructive reading; and although in some cases the desire for simplicity leads to a certain superficiality, this reproach cannot be fairly applied to their mathematical literature as a whole. Every reasonable person must admit that the simplest way of demonstrating a mathematical truth is the best one; and that energy wasted on the rudiments is so much loss of valuable time which might have been spent with profit otherwise.

The "New Plane and Solid Geometry," which is a revised edition of a work first published in 1895, illustrates very well the attitude of two experienced and competent American professors towards the problem of teaching elementary geometry. It is not to be expected that their work will meet with universal approval in all its details; but it has many conspicuous merits which cannot fail to commend themselves, and deserves to be carefully studied by every teacher, whatever his personal views may be.

The first thing to notice is the order and proportion which the authors have succeeded in maintaining. After a short, but very useful, introduction, there are eight Books dealing respectively with rectilineal figures; equality of polygons; circles; ratio and proportion; mensuration and regular polygons; lines and planes in

space; polyhedra; the cylinder, cone and sphere, and similar solids. At the end of the book will be found numerical tables, a biographical table, a table of etymologies and an index. The space allotted to the different sections is comparable with their relative importance, and proper emphasis is laid on fundamental ideas such as congruence, symmetry and similarity.

Another very important feature is that the student is consistently stimulated and encouraged to think for himself. Marginal queries are frequently inserted, in order that he may justify the statements in the text; and some of the proofs are given merely in outline for the reader to fill up in detail. On the other hand, figures and hints are given with the more difficult exercises. The appendix to Book iii., and other paragraphs inserted from time to time, ought to be of great help in teaching the student how to acquire the difficult art of proceeding from the unknown to the known by the method of analysis.

In the theory of parallels, the authors adopt Playfair's axiom; and their treatment of ratio is entirely arithmetical. In their opinion the purely geometric treatment is too difficult for the beginner. On this point opinions differ, and will probably continue to do so: at the same time the arithmetical theory is here given in as nearly rigorous a form as the beginner is likely to appreciate. Thus it is properly stated as an assumption that a geometric magnitude may be represented by a number; and the transition from the commensurable to the incommensurable case is made by the classic process of exhaustion. Of course the strict arithmetical theory is at least as hard as the geometrical one, because it involves, besides the assumption above stated, either Dedekind's theory of irrational numbers or something equivalent to it.[1] But there is something to be said in favour of beginning with a provisional theory, admittedly imperfect, o be made more precise later on. It would be easy to add, in a future edition, an appendix giving the strict arithmetical and geometrical theories.

In the discussion of the mensuration of the circle and other similar questions, the authors have avoided an error into which writers who adopt the arithmetical method are very apt to fall. They explicitly state the assumption that the circumference of a circle is the limit of the perimeter of an inscribed or circumscribed regular polygon, and then make use of the proved proposition that if, while approaching their respective limits, two variables have a constant ratio, their limits have that ratio. It is rather curious, by the by, that they omit to prove that the volume of a pyramid is the limit of the sum of the volumes of the usual set of inscribed prisms.

In the text, which is beautifully printed by the Athenæum Press, free use is made of abbreviations. The notation *ab* for the rectangle contained by the segments denoted by *a* and *b* will be objected to by some people; but it really needs no justification, because the analogy which it suggests is too useful to be ignored, and if the student cannot, after due warning, distinguish *ab*, the area of a rectangle, from *ab*, the product of two numbers, it is entirely his own fault.

The figures are very good; those on solid geometry have been very carefully drawn, and are nearly as effective as models would be. This is a great help to the beginner: he should bear in mind, however, that he must eventually be able to use a less pictorial figure, or even construct a diagram mentally in cases where an actual figure is too complicated to be useful. We should be rather inclined to suggest beginning with the more pictorial figures, and gradually reducing them to pure diagrams. Between a picture and a diagram there is the same sort of difference as there is between a photograph of an electrometer and a working drawing of the same instrument.

G. B. M.

[1] It may be remarked, in passing, that Euclid's test of the equality of two ratios really amounts to the establishment of the identity of two *Schnitte*, as Dedekind calls them; for if $mA >=< nB$ according as $mC >=< nD$, the series of rational numbers $m/n$ for which $mA > nB$ defines a *Schnitt*, and this is identical with the series for which $mC > nD$.

## OUR BOOK SHELF.

*An Elementary Course of Mathematics.* By H. S. Hall and F. H. Stevens. Pp. ix + 342. (London: Macmillan and Co., Ltd., 1899.)

IN preparing this book the object kept in mind was, as we are told in the preface, to provide in a simple and inexpensive volume a short course of arithmetic, algebra and Euclid specially adapted to the requirements of students who, after leaving school, desire to continue their study of elementary mathematics by partly attending evening classes and partly working privately at home.

To attain the end in view, the compilers, in the first portion on arithmetic, have restricted themselves to simply providing the student with a series of progressive exercises arranged to extend over a winter session of thirty weeks; a few additions, exercises with notes and hints, conclude this portion.

Algebra is next dealt with, and no previous knowledge is here assumed, so that a progressive but elementary course with numerous examples is given, covering the usual ground up to quadratic equations. In the last section on Euclid only the first book is considered. In the case of each proposition a few notes and exercises will help the reader to master this book, while additional theorems and a large set of appropriate examples are added for further practice.

For the purpose for which it is intended, this elementary course is well adapted.

*Carvell's Nursery Handbook, with Hints.* By J. M. Carvell. Pp. 70. (London: Barber, 1899.)

THE contents of this "Nursery Handbook" are arranged under a number of headings; for instance, "The Nursery," "Sleeping," "Clothing," "Feeding," &c. But in each section the hints given seem to be selected at haphazard; small details in some places are noted, while many points of importance are omitted.

In fact, the book seems too disjointed to be of real value, and the information too scanty to serve as a practical guide. In many instances the directions are so short that without amplification they might easily be misinterpreted.

*Chats about the Microscope.* By Henry C. Shelley. Pp. 101. (London: The Scientific Press, Ltd., 1899.)

YOUNG naturalists will find in this volume many useful hints on the collection and preparation of common objects for microscopical study, and will be guided to make observations of a number of minute organisms easily obtained.

## LETTERS TO THE EDITOR.

*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

### The Life of a Star.

THE letter of Prof. Perry on "The Life of a Star," published in your issue of July 13, is of interest to astronomers; and as the author of it evidently aims to be fair, I think it worth while to set right a misconception into which he has fallen. His reference to my paper in the *Astronomical Journal* (No. 455) shows that he has misconstrued the meaning of the symbol K in the formula $T = \frac{K}{R}$. That paper was unfortunately very much abbreviated, and as I was not concerned with the analytical investigation of K, this constant was not sufficiently explained. Yet in my first note on this law in the *A. J.* (453), which he probably overlooked, it was announced that "K is a constant different for each body." Thus the constant K is not, as Prof. Perry supposes, the same for the whole universe, but varies from star to star, being a function of the mass, specific heat, emissive power, &c., into which we need not go at present.

At the time of writing the paper in the *A. J.* (455) I had not seen the early paper by Ritter in *Wiedemann's Annalen*, 1878, s. 543,[1] where he has reached by a different process a similar formula

$$T_0 r_0 = Tr,$$

and anticipated a number of the conclusions to which I came independently. Ritter even applied this law to the temperature of the solar nebula when its periphery extended to the orbit of Neptune, and sagaciously observes that his conclusions do not agree with current views, but are yet uncontradicted by known facts.

As I have prepared for the St. Louis Academy of Sciences a paper in which this whole matter is discussed with some detail, I will here merely summarise a few of the chief results. Suffice it to say that the formula $T = \frac{K}{R}$ is shown to express a law of the utmost generality, for masses composed of one kind of gas; and that even when the body is of heterogeneous constitution, made up of interpenetrating globes of different gases, the law suffers no essential modification except at very long intervals, when it would take the form

$$T = \frac{K(1 + \beta t)}{R},$$

where $\beta$ is a certain small secular coefficient, and $t$ the time. For a great epoch the term depending on $\beta$ might be wholly neglected.

The only hypothesis underlying the investigation is that of convective equilibrium, the validity of which is generally recognised by physical investigators. In order that the reader may see how far from metaphysical my argument really is, I add an elementary derivation of the law of temperature.

Suppose a gaseous globe of radius $R_0$ to be held in convective equilibrium by the attraction, pressure and temperature of its particles (the density and temperature decreasing from the centre to the surface), and let the temperature beneath the surface layer be $T_0$. Let $P_0$ be the gravitational attraction exerted upon the thin layer of matter covering a unit surface of the globe, which may be regarded as the base of an elemental cone extending to the centre. Then suppose the globe to shrink by loss of heat to a radius R. If the original element of mass still covered a unit area, the pressure exerted upon its lower surface would thereby become $P = P_0\left(\frac{R_0}{R}\right)^2$. But since the area of the initial sphere surface has shrunk to $S = S_0\left(\frac{R}{R_0}\right)^2$, the area of the elemental conical base has diminished in the same ratio. As the force of gravity is increased, while the area upon which the element presses is decreased correspondingly, it follows that in the condensed condition of the globe, the gravitational pressure exerted upon a unit area is $P = P_0\left(\frac{R_0}{R}\right)^4$. The forces counteracting this increased pressure are obviously the resistance due to the increase in the mean density, and a possible change in temperature which might affect the elasticity of the gas. But the density of the original mass was $\sigma_0$, and hence $\sigma = \sigma_0\left(\frac{R_0}{R}\right)$. By hypothesis the equilibrium of the globe is maintained by the elastic force of the gas under the heat developed by the gravitational shrinkage of the mass. If therefore the globe was in equilibrium when the gas just beneath the surface layer had a mean temperature $T_0$, to remain in equilibrium in the condensed condition, $T_0$ must be multiplied by $\frac{R_0}{R}$. As $T_0 R_0$ = constant, we may write the law of temperature.

$$T = \frac{K}{R}.$$

This law of course applies to each layer of the globe, and thus to its mean temperature, and is obviously general for all gaseous celestial bodies condensing under the law of gravitation. Some persons who do not fully understand the problem under consideration have asserted that the functions which express the distribution of density and temperature with respect to the radius, are altered by shrinkage, so that the law then breaks down, or rather is not proved to hold true. It is perhaps worth while to show the error of this view.

Lord Kelvin has shown (*Phil. Mag.*, 1887, p. 287) that the temperature distribution throughout the globe must satisfy the differential equation

$$\frac{d^2\theta}{dx^2} + \frac{\theta^\kappa}{x^4} = 0,$$

where $\theta$ is the temperature, $x$ a function of the radius, and $\kappa$ a constant. If $\theta = \phi(x)$ be a particular solution of this equation, the second differential coefficients

$$\phi''(x) = -\{\phi(x)\}^\kappa x^{-4},$$

and

$$\phi''(\mu x) = -\{\phi(\mu x)\}^\kappa \mu^{-4} x^{-4};$$

and the general solution is shown to be of the form

$$\theta = C\phi\{xC^{-\frac{1}{4}}(\kappa^{-1})\},$$

where C and $\kappa$ are constants.

Under convective equilibrium the mass will contract in such a way that the particles in any concentric sphere surface do not penetrate those surfaces adjacent, that is, the new ordinate $\xi$ of any particle is defined by the equation $\xi = \alpha x$, where $\alpha$ is a numerical coefficient smaller than unity; and hence

$$\theta = C\phi\{\xi C^{-}(\kappa^{-1})\}$$

will be a solution of exactly the same form as the first. A curve defined by the equation

$$y = \psi(r^{-1})$$

will give the absolute temperature from the centre to the surface. In like manner another curve

$$\eta = \{\psi(r^{-1})\}^\kappa$$

will give the distribution of density with respect to the radius.

Shrinkage by which the variables become $\rho = \alpha r$ will not change the character of these two functions; and hence the distribution of density and temperature is rigorously the same after contraction as before. This result continues to hold so long as the body is wholly gaseous and obeys the laws of convective equilibrium.

Prof. Perry has examined at some length the question of radiation, and he deserves our thanks for the interesting suggestions he has advanced. Yet I have considered our knowledge based on terrestrial experiment too limited to furnish any conclusion which can be confidently applied to the conditions existing in the heavens, except that the masses are always in convective equilibrium, and that all shrinkage is determined by this condition. Accordingly the foregoing conclusions would seem to be valid generally. It seems fair to conclude that there are few branches of physical science which offer such an unexplored field as the one which relates to the life-history of stars. And though it may be assumed that forces are at work in space, of which we have little or no experimental analogy up to this time, yet it is always safe to apply known laws to the phenomena of the heavens with a view of explaining observations, and of suggesting unknown causes which may become the subject of future research.

Washington, D.C., August 5.

[1] Prof. Nipher, in preparing the excellent papers which he has contributed to the St. Louis Academy of Sciences, first drew attention to this reference.

### Remarkable Lightning Flashes.

LAST September you kindly published a photograph of a multiple lightning flash taken with a moving camera. I now enclose a photograph taken at Johannesburg by Mr. G. H. Preston. I think that he must have moved his camera (Frena) unintentionally, being startled at the commencement of a very vivid flash, which seems to have lasted some considerable time, say nearly one second. At any rate there are nine distinct lightning flashes, all of identical shape. The first three, or perhaps a few more, are very strong and close together, and possibly while they were taken the camera may as yet have been

fairly stationary; its axis then moved in spiral curves while the remaining six flashes imprinted themselves.

The photograph is of interest on account of the large number of individual but otherwise identical flashes, and especially because it shows that these individual discharges follow each other at irregular intervals; and I hope that the suggestion which I made last year to study this subject may be carried out.

As on my last year's photograph, there is on this one an additional flash, which appears to be single but is much more branched than the other one. C. E. STROMEYER.

Lancefield, West Didsbury, August 21.

---

IN NATURE for September 14 (p. 460), the writer on dark lightning refers to the absence of dark flashes in pictures of artificial discharge. I may perhaps draw the attention of any who are unfamiliar with Lord Armstrong's "Electric Movement in Air and Water" to Plate 34 in that book, in which is shown a very fine example of a dark fla h. Lord Armstrong describes how he obtained the discharge on p. 41. Plate 18 is also of interest in this connection. HENRY STROUD.

The Durham College of Science, Newcastle-upon-Tyne, September 18.

---

I DO not see on what grounds it is concluded (p. 423) that ribbon lightning has a real existence. The appearance might easily be caused by defective vision. If the fork is not distinctly focussed on the retina, it may appear either broadened or double or multiple, especially if there is any degree of cataract in the eye. The ribbon appearance in the photograph shown in your article is surely to be explained by the camera having been moved downwards and slightly to the right, or else in the opposite direction, and three or more discharges having taken place during the time. The horizon not being sharp is further evidence. One may imagine, however, that an appearance of this kind might also arise from a discharge being repeated through the same air, but the air moving bodily between one discharge and the next: it seems to me it yet remains to be proved whether such a thing ever does occur. One would suppose that if it did, the motion of the air would not be uniform throughout the flash, and therefore the ribbon would be unequal in width in different parts.

With regard to apparently black lightning, some months ago I saw a black fork having exactly the appearance of an ordinary flash of forked lightning, only dark on the light ground of a flash of sheet lightning. I concluded the explanation to be that given by Lord Kelvin, only the curious circumstance was that I did not remember I had previously seen a bright fork of the pattern of the dark one. I have no doubt, however, that there must have been one, and that my being dazzled by it caused me to see it again, dark, as soon as there was a light background to show it. T. W. BACKHOUSE.

West Hendon House, Sunderland, September 18.

---

IT is surprising that such a brilliant experimentalist as Prof. R. W. Wood does not allude to that peculiar reversal of the photographic image known as the Clayden effect.

I drew particular attention to this explanation of the dark flash in a lecture before the Royal Photographic Society this year, which is fully reported and illustrated in the *Photographic Journal* for March last.

The Clayden effect is easily verified in the following way.

Arrange the sparking terminals of a coil, horizontally, about four inches apart, with a dark background of velvet; focus a camera for the sparks, then darken the room. Place a strip of white card one inch wide near one terminal in the spark gap, uncap the lens, and expose on the card by burning one inch of magnesium wire; then remove the card and pass a spark, now place the same card near the other terminal of the spark gap, and burn another inch of magnesium wire. On developing the plate it will be found that the spark image is reversed over the latter card only.

This shows that the same amount of fog has a very different effect, whether it is deposited before or after the image. It must sometimes happen that in photographing lightning some sky fog or other fog will be deposited after the image; it therefore seems highly probable that any bright flash could be converted into a dark flash by slightly fogging the plate before development. The Clayden effect also explains why, with a number of flashes on the same plate, some may be dark and some light, and yet dark lightning probably has no real existence.

### Sedge-Warblers seizing Butterflies.

OBSERVED instances of birds capturing butterflies are so few that I venture to think the following worth putting on record. On the evening of August 12, at about 6.30 p.m., I was walking beside a dyke on Ludham Marsh, Norfolk, when my attention was attracted by the alarm notes of a pair of sedge-warblers in the reeds. I stood still, and soon caught sight of both birds within about six yards of me. Each had a butterfly in its mouth, and with my field-glass I was able to identify the species as a meadow brown (*E. Janira*) and a small white (*P. rapae*). From the behaviour of the birds, and my observation of them on subsequent days, I have no doubt that they were feeding their nestlings, though I was unable to find the nest. I may add that at the time most of the butterflies had taken up their quarters for the night on stems of reeds, &c., and that very many of the butterflies which I observed during the daytime on the marshes had very ragged and chipped wings. These injuries may have been caused by wind and contact with twigs, thorns, &c., but they were quite compatible with repeated ineffectual pecks and snips from the beaks of small birds.

### Explosion of Aluminium Iodide.

I HAD two samples of aluminium iodide in two hermetically sealed glass tubes sent by a German firm. One of them was passing round the class, and the other was lying on the demonstration table. Suddenly a report was heard, and I found that the tube on the table had exploded, and its contents had been thrown out. Both the tubes were perfectly sound, and therefore there seems to be no reason to suspect that the volatile compound found an explosive mixture with the air. The temperature of the lecture room was at the time nearly 95° F. I communicate this matter to you to find out if others have had similar experience with aluminium iodide. P. L. NARASU.

Christian College, Madras, July 30.

## THE DOVER MEETING OF THE BRITISH ASSOCIATION.

THE final meeting of the general committee of the British Association was held on Wednesday in last week, for the purpose of receiving the report of the committee of recommendations. The list of grants made for various scientific purposes has already been given (p. 496). The committee also recommended that, in view of the opportunities of ethnographic inquiry which will be presented by the Indian census now beginning, the council of the Association be requested to urge the Government of India to make use of the census officers to obtain information with reference to particular races and tribes, and to attach photographers to the census officers to furnish a complete photographic series of typical specimens of the various races, of views of archaic industries, and of other facts interesting to ethnologists. This recommendation was accepted and ordered to be forwarded to the council. It was also resolved that the council be requested to recommend to Her Majesty's Government the importance of giving more prominence to botany in the training of Indian forest officers.

At the concluding general meeting of the Association, held on Wednesday, September 20, it was announced that the number of tickets issued was 1403. The usual votes of thanks were then put to the meeting and passed.

Sir G. G. Stokes proposed :—"That the best thanks of the Association be given to the Mayor and Corporation, to the local committee, and to the officers of the local sub-committees for their reception of the Association." Prof. Forsyth, in seconding the resolution, said that they should all carry away grateful recollections of the way in which they had been treated at Dover, and if the meeting had not been the largest it had certainly been very pleasant and highly successful.

The two local secretaries, Colonel Knocker and Mr. W. H. Pendlebury, responded for the local committee.

Sir John Evans proposed a vote of thanks to the President, Council, and Headmaster of Dover College for putting the college buildings at the service of the Association. In seconding the resolution Sir W. Thiselton-Dyer expressed, on behalf of the members of the Association, gratitude to the municipality and inhabitants of Dover for the reception which they had given to the Association. Some of the work this year had been of quite exceptional importance.

The Headmaster of Dover College (the Rev. W. C. Compton) acknowledged the vote of thanks.

Sir Norman Lockyer proposed a vote of thanks to Captain Winslow and the other officers of Her Majesty's ships, to Major-General Sir Leslie Rundle and Staff, and to all the inhabitants who had entertained members or conducted excursions, and to the heads of firms who had thrown open their works. He remarked that the fact that this vote of thanks included officers of Her Majesty's Navy and Army gave distinction to a meeting which otherwise had a distinctive character. For the first time members of the Association had met in the Sections together with French *confrères*, and the visit of the French Association had been marked by many little incidents showing a kindly feeling, which was national rather than local.

Sir W. H. White seconded the resolution, and Dr. Sebastian Evans briefly responded.

Sir John Murray moved that a cordial vote of thanks be given to Sir Michael Foster for his services as president of the Dover meeting.

Sir A. Binnie, in seconding the resolution, said that the success of this meeting was largely due to the tact and urbanity of the president. Sir Michael Foster in a few words acknowledged the compliment, and then declared the meeting adjourned till next September at Bradford.

On Wednesday afternoon the Mayor and Corporation of Canterbury received and entertained at luncheon the president and some of the chief officers of the Association, together with the president, Dr. Brouardel, and about a hundred members of l'Association française pour l'avancement des sciences

A brief toast list followed the luncheon. The Queen and the President of the French Republic having been successively proposed from the chair, Dean Farrar gave "Our Guests and Success to the British and French Associations for the Advancement of Science," coupling with it the names of the presidents of the two Associations. In the course of his remarks he said there was no means of human knowledge which the human mind could devote itself to study with more profit or advantage than the knowledge of science. It was right to do honour to those whose efforts had illuminated darkness, removed ignorance and extended man's horizon.

Dr. Brouardel and Sir Michael Foster responded.

On Thursday, September 21, the president, officials and about three hundred members of the British Association proceeded from Dover to Boulogne to return the visit of the French Association. From the *Times* report we learn that at Boulogne they were received by leading members of the French Association, who entertained them to breakfast, and afterwards they were officially welcomed at the Town Hall by the Mayor of Boulogne. Later in the day they were entertained at a banquet in the ball-room of the casino by the municipality of the town, and speeches of compliment and welcome were delivered by the Prefect of the Pas de Calais, the Director of Primary Education as delegate of the French Government, Sir Michael Foster and Dr. Brouardel. Special commemorative medals were presented by the French Association to their president and Sir M. Foster. Subsequently the visitors were present at the unveiling of a monument of Dr. Duchesne—who died about twenty-five years ago and was distinguished by his application of electricity to nervous disorders—and of a black marble plaque upon the house in which Thomas Campbell, the poet (who devoted much time and attention to many public matters, including the University of London), died at Boulogne in 1844.

No account of the meeting which has just been concluded would be complete without a reference to two sermons on "Some of the Mutual Influences of Theology and the Natural Sciences," preached in St Mary's Church for members of the Association by the Ven. J. M. Wilson, Archdeacon of Manchester. The enlarged conception of the study of theology, as presented by Archdeacon Wilson, will be made the subject of deep consideration by many thoughtful minds ; and men of science cannot but be gratified at the liberal spirit which permeated it. No longer is it asserted that the methods and results of theology and science are antagonistic, but rather that the two exert beneficial influences upon each other, and that the scientific method should be applied to theological research. The expression of such rational views should do much to overcome the prejudice which still exists against scientific habits of thought, and to create sympathy between men engaged in advancing natural and theological knowledge. The common meeting ground is the search for truth, so far as the human mind can follow it.

### SECTION E.

#### GEOGRAPHY.

OPENING ADDRESS BY SIR JOHN MURRAY, K.C.B., F.R.S., LL.D., PRESIDENT OF THE SECTION.

IN his opening Address to the members of the British Association at the Ipswich meeting, the President cast a retrospective glance at the progress that had taken place in the several branches of scientific inquiry from the time of the formation of the Association in 1831 down to 1895, the year in which

were published the last two of the fifty volumes of Reports containing the scientific results of the voyage of H.M.S. *Challenger*. In that very able and detailed review there is no reference whatever to the work of the numerous expeditions which had been fitted out by this and other countries for the exploration of the depths of the sea, nor is there any mention of the great advance in our knowledge of the ocean during the period of sixty-five years then under consideration. This omission may be accounted for by the fact that, at the time of the formation of the British Association, knowledge concerning the ocean was, literally speaking, superficial. The study of marine phenomena had hitherto been almost entirely limited to the surface and shallow waters of the ocean, to the survey of coasts and of oceanic routes directly useful for commercial purposes. Down to that time there had been no systematic attempts to ascertain the physical and biological conditions of those regions of the earth's surface covered by the deeper waters of the ocean; indeed, most of the apparatus necessary for such investigations had not yet been invented.

The difficulties connected with the exploration of the greater depths of the sea arise principally from the fact that, in the majority of cases, the observations are necessarily indirect. At the surface of the ocean direct observation is possible, but our knowledge of the conditions prevailing in deep water, and of all that is there taking place, is almost wholly dependent on the correct working of instruments, the action of which at the critical moment is hidden from sight.

It was the desire to establish telegraphic communication between Europe and America that gave the first direct impulse to the scientific exploration of the great ocean-basins, and at the present day the survey of new cable routes still yields each year a large amount of accurate knowledge regarding the floor of the ocean. Immediately before the *Challenger* Expedition there was a marked improvement in all the apparatus used in marine investigations, and thus during the *Challenger* Expedition the great ocean-basins were for the first time systematically and successfully explored. This expedition, which lasted for nearly four years, was successful beyond the expectations of its promoters, and opened out a new era in the study of oceanography. A great many sciences were enriched by a grand accumulation of new facts. Large collections were sent and brought home, and were subsequently described by specialists belonging to almost every civilised nation. Since the *Challenger* Expedition there has been almost a revolution in the methods employed in deep-sea observations. The most profound abysses of the ocean are now being everywhere examined by sailors and scientific men with increasing precision, rapidity and success.

The recognition of oceanography as a distinct branch of science may be said to date from the commencement of the *Challenger* investigations. The fuller knowledge we now possess about all oceanic phenomena has had a great modifying influence on many general conceptions as to the nature and extent of those changes which the crust of the earth is now undergoing and has undergone in past geological times Our knowledge of the ocean is still very incomplete. So much has, however, already been acquired that the historian will, in all probability, point to the oceanographical discoveries during the past forty years as the most important addition to the natural knowledge of our planet since the great geographical voyages associated with the names of Columbus, Da Gama, and Magellan, at the end of the fifteenth and the beginning of the sixteenth centuries.

It is not my intention on this occasion to attempt anyth ng like a general review of the present state of oceanographic science. But, as nearly all the samples of marine deposits collected during the past thirty years have passed through my hands, I shall endeavour briefly to point out what, in general, their detailed examination teaches with respect to the present condition of the floor of the ocean, and I will thereafter indicate what appears to me to be the bearing of some of these results on speculations as to the evolution of the existing surface features of our planet.

### *Depth of the Ocean.*

All measurements of depth, by which we ascertain the relief of that part of the earth's crust covered by water, are referred to the sea-surface; the measurements of height on the land are likewise referred to sea-level. It is admitted that the ocean has a very complicated undulating surface, in consequence of the attraction which the heterogeneous and elevated portions of the lithosphere exercise on the liquid hydrosphere. In the opinion of geodesists the geoid may in some places depart from the figure of the spheroid by 1000 feet. Still it is not likely that this surface of the geoid departs so widely from the mean ellipsoidal form as to introduce a great error into our estimates of the elevations and depressions on the surface of the lithosphere.

The soundings over the water-surface of the globe have accumulated at a rapid rate during the past fifty years. In the shallow water, where it is necessary to know the depth for purposes of navigation, the soundings may now be spoken of as innumerable; the 100-fathom line surrounding the land can therefore often be drawn in with much exactness. Compared with this shallow-water region, the soundings in deep water beyond the 100-fathom line are much less numerous; each year, however, there are large additions to our knowledge. Within the last decade over ten thousand deep soundings have been taken by British ships alone. The deep soundings are scattered over the different ocean-basins in varying proportions, being now most numerous in the North Atlantic and South-west Pacific, and in these two regions the contour-lines of depth may be drawn in with greater confidence than in the other divisions of the great ocean-basins. It may be pointed out that 659 soundings taken quite recently during cable surveys in the North Atlantic, although much closer together than is usually the case, and yielding much detailed information to cable engineers, have, from a general point of view, necessitated but little alteration in the contour-lines drawn on the *Challenger* bathymetrical maps published in 1895. Again, the recent soundings of the German s.s. *Valdivia* in the Atlantic, Indian, and Southern Oceans have not caused very great alteration in the positions of the contour-lines on the *Challenger* maps, if we except one occasion in the South Atlantic when a depth of 2000 fathoms was expected and the sounding machine recorded a depth of only 536 fathoms, and again in the great Southern Ocean when depths exceeding 3000 fathoms were obtained in a region where the contour-lines indicated between 1000 and 2000 fathoms. This latter discovery suggests that the great depth recorded by Ross to the south-east of South Georgia may not be very far from the truth.

I have redrawn the several contour-lines of depth in the great ocean-basins, after careful consideration of the most recent data, and these may now be regarded as a somewhat close approximation to the actual state of matters, with the possible exception of the great Southern and Antarctic Oceans, where there are relatively few soundings, but where the projected Antarctic Expeditions should soon be at work. On the whole, it may be said that the general tendency of recent soundings is to extend the area with depths greater than 1000 fathoms, and to show that numerous volcanic cones rise from the general level of the floor of the ocean-basins up to various levels beneath the sea-surface.

The areas marked out by the contour-lines of depth are now estimated as follows:—

| | Fms. | Sq. geo. m. | Per cent. |
|---|---|---|---|
| Between the shore and | 100 | ... 7,000,000 | ... (or 7 of the sea-bed) |
| ,, 100 ,, | 1000 | .. 10,000,000 | ... (or 10 ,, ,, ) |
| ,, 1000 ,, | 2000 | ... 22,000,000 | ... (or 21 ,, ,, ) |
| ,, 2000 ,, | 3000 | ... 57,000,000 | ... (or 55 ,, ,, ) |
| Over 3000 fathoms | ... | ... 7,000,000 | ... (or 7 ,, ,, ) |
| | | 103,000,000 | 100 |

From these results it appears that considerably more than half of the sea-floor lies at a depth exceeding 2000 fathoms, or over two geographical miles. It is interesting to note that the area within the 100 fathom line occupies 7,000,000 square geographical miles, whereas the area occupied by the next succeeding 900 fathoms (viz. between 100 and 1000 fathoms) occupies only 10,000,000 square geographical miles. This points to a relatively rapid descent of the sea-floor along the continental slopes between 100 and 1000 fathoms, and therefore confirms the results gained by actual soundings in this region, many of which indicate steep inclines or even perpendicular cliffs. Not only are the continental slopes the seat of many deposit-slips and seismic disturbances, but Mr. Benest has given good reasons for believing that underground rivers sometimes enter the sea at depths beyond 100 fathoms, and there bring about sudden changes in deep water. Again, the relatively large area covered by the continental shelf between the shore-line and 100 fathoms points to the wearing away of the land by current and wave action.

On the *Challenger* charts all areas where the depth exceeds

3000 fathoms have been called "Deeps," and distinctive names have been conferred upon them. Forty-three such depressions are now known, and the positions of these are shown on the map here exhibited; twenty-four are situated in the Pacific Ocean, three in the Indian Ocean, fifteen in the Atlantic Ocean, and one in the Southern and Antarctic Oceans. The area occupied by these thirty-nine deeps is estimated at 7,152,000 square geographical miles, or about 7 per cent. of the total water-surface of the globe. Within these deeps over 250 soundings have been recorded, of which twenty-four exceed 4000 fathoms, including three exceeding 5000 fathoms.

Depths exceeding 4000 fathoms (or four geographical miles) have been recorded within eight of the deeps, viz. in the North Atlantic within the Nares Deep; in the Antarctic within the Ross Deep; in the Banda Sea within the Weber Deep; in the North Pacific within the Challenger, Tuscarora, and Supau Deeps; and in the South Pacific within the Aldrich and Richards Deeps. Depths exceeding 5000 fathoms have been hitherto recorded only within the Aldrich Deep of the South Pacific, to the east of the Kermadecs and Friendly Islands, where the greatest depth is 5155 fathoms, or 530 feet more than five geographical miles, being about 2000 feet more below the level of the sea than the summit of Mount Everest in the Himalayas is above it. The levels on the surface of the lithosphere thus oscillate between the limits of about ten geographical miles (more than eighteen kilometres).

*Temperature of the Ocean-floor.*

Our knowledge of the temperature on the floor of the ocean is derived from observations in the layers of water immediately above the bottom by means of deep-sea thermometers, from the electric resistance of telegraph cables resting on the bed of the great ocean-basins, and from the temperature of large masses of mud and ooze brought up by the dredge from great depths. These observations are now sufficiently numerous to permit of some general statements as to the distribution of temperature over the bottom of the great oceans.

All the temperatures recorded up to the present time in the sub-surface waters of the open ocean indicate that at a depth of about 100 fathoms seasonal variation of temperature disappears. Beyond that depth there is a constant, or nearly constant, temperature at any one place throughout the year. In some special positions, and under some peculiar conditions, a lateral shifting of large bodies of water takes place on the floor of the ocean at depths greater than 100 fathoms. This phenomenon has been well illustrated by Prof. Libbey off the east coast of North America, where the Gulf Stream and Labrador Current run side by side in opposite directions. This lateral shifting cannot, however, be called seasonal, for it appears to be effected by violent storms, or strong off-shore winds bringing up colder water from considerable depths to supply the place of the surface drift, so that the colder water covers stretches of the ocean's bed which under normal conditions are overlaid by warmer strata of water. Sudden changes of temperature like these cause the destruction of innumerable marine animals, and produce very marked peculiarities in the deposits over the areas thus affected.

It is estimated that 92 per cent. of the entire sea-floor has a temperature lower than 40° F. This is in striking contrast to the temperature prevailing at the surface of the ocean, only 16 per cent. of which has a mean temperature under 40° F. The temperature over nearly the whole of the floor of the Indian Ocean in deep water is under 35° F. A similar temperature occurs over a large part of the South Atlantic and certain parts of the Pacific, but at the bottom of the North Atlantic basin and over a very large portion of the Pacific the temperature is higher than 35° F. In depths beyond 2000 fathoms, the average temperature over the floor of the North Atlantic is about 2° F. above the average temperature at the bottom of the Indian Ocean and South Atlantic, while the average temperature of the bed of the Pacific is intermediate between these.

It is admitted that the low temperature of the deep sea has been acquired at the surface in Polar and sub-Polar regions, chiefly within the higher latitudes of the southern hemisphere, where the cooled surface water sinks to the bottom and spreads slowly over the floor of the ocean into equatorial regions. These cold waters carry with them into the deep sea the gases of the atmosphere, which are everywhere taken up at the surface according to the known laws of gas absorption. In this way myriads of living animals are enabled to carry on their existence at all depths in the open ocean. The nitrogen remains more or less constant at all times and places, but the proportion of oxygen is frequently much reduced in deep water, owing to the processes of oxidation and respiration which are there going on.

The deep sea is a region of darkness as well as of low temperature, for the direct rays of the sun are wholly absorbed in passing through the superficial layers of water. Plant-life is in consequence quite absent over 93 per cent. of the bottom of the ocean, or 66 per cent. of the whole surface of the lithosphere. The abundant deep-sea fauna, which covers the floor of the ocean, is therefore ultimately dependent for food upon organic matter assimilated by plants near its surface, in the shallower waters near the coast-lines, and on the surface of the dry land itself.

As has been already stated, about 7,000,000 square geographical miles of the sea-floor lies within the 100-fathom line, and this area is in consequence subject to seasonal variations of temperature, to strong currents, to the effects of sunlight, and presents a great variety of physical conditions. The planktonic plant-life is here reinforced by the littoral sea-weeds, and animal-life is very abundant. About 40 per cent. of the water over the bottom of this shallow-water area has a mean temperature under 40° F., while 20 per cent. has a mean temperature between 40° and 60° F., and 40 per cent. a temperature of over 60° F.

It follows from this that only 3 per cent. of the floor of the ocean presents conditions of temperature favourable for the vigorous growth of corals and those other benthonic organisms which make up coral reefs and require a temperature of over 60° F. all the year round. On the other hand, more than half of the surface of the ocean has a temperature which never falls below 60° F. at any time of the year. In these surface-waters with a high temperature, the shells of Pelagic Molluscs, Foraminifera, Algæ, and other planktonic organisms are secreted in great abundance, and fall to the bottom after death.

It thus happens that, at the present time, over nearly the whole floor of the ocean we have mingled in the deposits the remains of organisms which had lived under widely different physical conditions, since the remains of organisms which lived in tropical sunlight, and in water at a temperature above 80° F., all their lives, now lie buried in the same deposit on the sea-floor together with the remains of other organisms which lived all their lives in darkness and at a temperature near to the freezing point of fresh water.

*Marine Deposits on the Ocean-floor.*

The marine deposits now forming over the floor of the ocean present many interesting peculiarities according to their geographical and bathymetrical position. On the continental shelf, within the 100-fathom line, sands and gravels predominate, while on the continental slopes beyond the 100-fathom line, Blue Muds, Green Muds, and Red Muds, together with Volcanic Muds and Coral Muds, prevail, the two latter kinds of deposits being, however, more characteristic of the shallow water around oceanic islands. The composition of all these Terrigenous Deposits depends on the structure of the adjoining land. Around continental shores, except where coral reefs, limestones, and volcanic rocks are present, the materials consist principally of fragments and minerals derived from the disintegration of the ancient rocks of the continents, the most characteristic and abundant mineral species being quartz. River detritus extends in many instances far from the land, while off high and bold coasts, where no large rivers enter the sea, pelagic conditions may be found in somewhat close proximity to the shore-line. It is in these latter positions that Green Muds containing much glauconite, and other deposits containing many phosphatic nodules, have for the most part been found; as, for instance, off the eastern coast of the United States, off the Cape of Good Hope, and off the eastern coasts of Australia and Japan. The presence of glauconitic grains and phosphatic nodules in the deposit at these places appears to be very intimately associated with a great annual range of temperature in the surface and shallow waters, and the consequent destruction of myriads of marine animals. As an example of this phenomenon may be mentioned the destruction of the tile-fish in the spring of 1882 off the eastern coast of North America, when a layer six feet in thickness of dead fish and other marine animals was believed to cover the ocean floor for many square miles.

In all the Terrigenous Deposits the evidences of the mechanical action of tides, of currents, and of a great variety of physical conditions, may almost everywhere be detected, and it is possible

to recognise in these deposits an accumulation of materials analogous to many of the marine stratified rocks of the continents, such as sandstones, quartzites, shales, marls, greensands, chalks, limestones, conglomerates, and volcanic grits.

With increasing depth and distance from the continents the deposits gradually lose their terrigenous character, the particles derived directly from the emerged land decrease in size and in number, the evidences of mechanical action disappear, and the deposits pass slowly into what have been called Pelagic Deposits at an average distance of about 200 miles from continental coast-lines. The materials composing Pelagic Deposits are not directly derived from the disintegration of the continents and other land-surfaces. They are largely made up of the shells and skeletons of marine organisms secreted in the surface waters of the ocean, consisting either of carbonate of lime, such as Pelagic Molluscs, Pelagic Foraminifera, and Pelagic Algæ, or of silica, such as Diatoms and Radiolarians. The inorganic constituents of the Pelagic Deposits are for the most part derived from the attrition of floating pumice, from the disintegration of water-logged pumice, from showers of volcanic ashes, and from the débris ejected from submarine volcanoes, together with the products of their decomposition. Quartz particles, which play so important a *rôle* in the Terrigenous Deposits, are almost wholly absent, except where the surface waters of the ocean are affected by floating ice, or where the prevailing winds have driven the desert sands far into the oceanic areas. Glauconite is likewise absent from these abysmal regions. The various kinds of Pelagic Deposits are named according to their characteristic constituents, Pteropod Oozes, Globigerina Oozes, Diatom Oozes, Radiolarian Oozes, and Red Clay.

The distribution of the deep-sea deposits over the floor of the ocean is shown on the map here exhibited, but it must be remembered that there is no sharp line of demarcation between them; the Terrigenous pass gradually into the Pelagic Deposits, and the varieties of each of these great divisions also pass insensibly the one into the other, so that it is often difficult to fix the name of a given sample.

On another map here exhibited the percentage distribution of carbonate of lime in the deposits over the floor of the ocean has been represented, the results being founded on an extremely large number of analyses. The results are also shown in the following table:—

| | Sq. Geo. Miles. | Percentage. |
|---|---|---|
| Over 75% $CaCO_3$ ... | 6,000,000 | 5·8 |
| 50 to 75% ,, ... | 24,000,000 | 23·2 |
| 25 to 50% ,, ... | 14,000,000 | 13·5 |
| Under 25% ,, ... | 59,000,000 | 57·5 |
| | 103,000,000 | 100 |

The carbonate of lime shells derived from the surface play a great and puzzling *rôle* in all deep-sea deposits, varying in abundance according to the depth of the ocean and the temperature of the surface waters. In tropical regions removed from land, where the depths are less than 600 fathoms, the carbonate of lime due to the remains of these organisms from the surface may rise to 80 or 90 per cent.; with increase of depth, and under the same surface conditions, the percentage of carbonate of lime slowly diminishes, till, at depths of about 2000 fathoms, the average percentage falls to about 60, at 2400 fathoms to about 30, and at about 2600 fathoms to about 10, beyond which depth there may be only traces of carbonate of lime due to the presence of surface shells. The thin and more delicate surface shells first disappear from the deposits, the thicker and denser ones alone persist to greater depths. A careful examination of a large number of observations shows that the percentage of carbonate of lime in the deposits falls off much more rapidly at depths between 2200 and 2500 fathoms than at other depths.

The Red Clay, which occurs in all the deeper stretches of the ocean far from land, and covers nearly half of the whole sea-floor, contains—in addition to volcanic débris, clayey matter, the oxides of iron and manganese—numerous remains of whales, sharks and other fishes, together with zeolitic crystals, manganese nodules, and minute magnetic spherules, which are believed to have a cosmic origin. One hawl of a small trawl in the Central Pacific brought to the surface on one occasion, from a depth of about two and a half miles, many bushels of manganese nodules, along with fifteen hundred sharks' teeth, over fifty fragments of earbones and other bones of whales. Some of these organic remains, such as the *Carcharodon* and *Lamna* teeth and the bones of the Ziphioid whales, belong apparently to extinct species. One or two of these sharks' teeth, ear-bones, or cosmic spherules, may be occasionally found in a Globigerina Ooze, but their occurrence in this or any deposits other than Red Clay is extremely rare.

Our knowledge of the marine deposits is limited to the superficial layers; as a rule, the sounding-tube does not penetrate more than six or eight inches, but in some positions the sounding-tube and dredge have been known to sink fully two feet into the deposit. Sometimes a Red Clay is overlaid by a Globigerina Ooze, more frequently a Red Clay overlies a Globigerina Ooze, the transition between the two layers being either abrupt or gradual. In some positions it is possible to account for these layers by referring them to changes in the condition of the surface waters, but in other situations it seems necessary to call in elevations and subsidences of the sea-floor.

If the whole of the carbonate of lime shells be removed by dilute acid from a typical sample of Globigerina Ooze, the inorganic residue left behind is quite similar in composition to a typical Red Clay. This suggests that possibly, owing to some hypogene action, such as the escape of carbonic acid through the sea-floor, a deposit that once was a Globigerina Ooze might be slowly converted into a Red Clay. However, this is not the interpretation which commends itself after an examination of all the data at present available; a consideration of the rate of accumulation probably affords a more correct interpretation. It appears certain that the Terrigenous Deposits accumulate much more rapidly than the Pelagic Deposits. Among the Pelagic Deposits, the Pteropod and Globigerina Oozes of the tropical regions, being made up of the calcareous shells of a much larger number of tropical species, apparently accumulate at a greater rate than the Globigerina Oozes in extra-tropical areas. Diatom Ooze being composed of both calcareous and siliceous organisms, has again a more rapid rate of deposition than Radiolarian Ooze. In Red Clay the minimum rate of accumulation takes place. The number of sharks' teeth, of earbones and other bones of Cetaceans and of cosmic spherules in a deposit may indeed be taken as a measure of the rate of deposition. These spherules, teeth and bones are probably more abundant in the Red Clays, because few other substances there fall to the bottom to cover them up, and they thus form an appreciable part of the whole deposit. The volcanic materials in a Red Clay having, because of the slow accumulation, been for a long time exposed to the action of sea-water, have been profoundly altered. The massive manganese-iron nodules and zeolitic crystals present in the deposit are secondary products arising from the decomposition of these volcanic materials, just as the formation of glauconite, phosphatic, and calcareous and barytic nodules accompanies the decomposition of terrigenous rocks and minerals in deposits nearer continental shores. There is thus a striking difference between the average chemical and mineralogical composition of Terrigenous and Pelagic Deposits.

It would be extremely interesting to have a detailed examination of one of those deep holes where a typical Red Clay is present, and even to bore some depth into such a deposit if possible, for in these positions it is probable that not more than a few feet of deposit have accumulated since the close of the Tertiary period. One such area lies to the south-west of Australia, and its examination might possibly form part of the programme of the approaching Antarctic explorations.

### *Life on the Ocean-floor.*

It has already been stated that plant-life is limited to the shallow waters, but fishes and members of all the invertebrate groups are distributed over the floor of the ocean at all depths. The majority of these deep-sea animals live by eating the mud, clay or ooze, or by catching the minute particles of organic matter which fall from the surface. It is probably not far from the truth to say that three-fourths of the deposits now covering the floor of the ocean have passed through the alimentary canals of marine animals. These mud-eating species, many of which are of gigantic size when compared with their allies living in the shallow coastal waters, become in turn the prey of numerous rapacious animals armed with peculiar prehensile and tactile organs. Some fishes are blind, while others have very large eyes. Phosphorescent light plays a most important *rôle* in the deep sea, and is correlated with the prevailing red and brown colours of deep-sea organisms. Phosphorescent organs appear sometimes to act as a bull's-eye lantern to enable particles of

food to be picked up, and at other times as a lure or a warning. All these peculiar adaptations indicate that the struggle for life may be not much less severe in the deep sea than in the shallower waters of the ocean.

Many deep-sea animals present archaic characters; still the deep sea cannot be said to contain more remnants of faunas which flourished in remote geological periods than the shallow and fresh waters of the continents. Indeed, king-crabs, Lingulas, Trigonias, Port Jackson sharks, *Ceratodus*, *Lepidosiren*, and *Protopterus*, probably represent older faunas than anything to be found in the deep sea

Sir Wyville Thomson was of opinion that, from the Silurian period to the present day, there had been as now a continuous deep ocean with a bottom temperature oscillating about the freezing point of fresh water, and that there had always been an abyssal fauna. I incline to the view that in Palæozoic times the ocean-basins were not so deep as they are now; that the ocean then had throughout a nearly uniform high temperature, and that life was either absent or represented only by bacteria and other low forms in great depths, as is now the case in the Black Sea, where life is practically absent beyond 100 fathoms, and where the deeper waters are saturated with sulphuretted hydrogen. This is not, however, the place to enter on speculations concerning the origin of the deep-sea fauna, nor to dwell on what has been called "bipolarity" in the distribution of marine organisms.

*Evolution of the Continental and Oceanic Areas.*

I have now pointed out what appears to me to be some of the more general results arrived at in recent years regarding the present condition of the floor of the ocean. I may now be permitted to indicate the possible bearing of these results on opinions as to the origin of some fundamental geographical phenomena; for instance, on the evolution of the protruding continents and sunken ocean-basins. In dealing with such a problem much that is hypothetical must necessarily be introduced, but these speculations are based on ascertained scientific facts.

The well-known American geologist, Dutton, says: "It has been much the habit of geologists to attempt to explain the progressive elevation of plateaus and mountain platforms, and also the folding of strata, by one and the same process. I hold the two processes to be distinct, and having no necessary relation to each other. There are plicated regions which are little or not at all elevated, and there are elevated regions which are not plicated." Speaking of great regional uplifts, he says further: "What the real nature of the uplifting force may be is, to my mind, an entire mystery, but I think we may discern at least one of its attributes, and that it is a gradual expansion or a diminution of density of the subterranean magmas. . . . We know of no cause which could either add to the mass or diminish the density, yet one of the two must surely have happened. . . . Hence I infer that the cause which elevates the land involves an expansion of the underlying magmas, and the cause which depresses it is a shrinkage of the magmas; the nature of the process is at present a complete mystery." I shall endeavour to show how the detailed study of marine deposits may help to solve the mystery here referred to by Dutton.

The surface of the globe has not always been as we now see it. When, in the past, the surface had a temperature of about 400° F., what is now the water of the ocean must have existed as water vapour in the atmosphere, which would thereby—as well as because of the presence of other substances—be increased in density and volume. Life, as we know it, could not then exist. Again, science foresees a time when low temperatures, like those produced by Prof. Dewar at the Royal Institution, will prevail over the face of the earth. The hydrosphere and atmosphere will then have disappeared within the rocky crust, or the waters of the ocean will have become solid rock, and over their surface will roll an ocean of liquid air about forty feet in depth. Life, as we know it, unless it undergoes suitable secular modifications, will be extinct. Somewhere between these two indefinite points of time in the evolution of our planet it is our privilege to live, to investigate, and to speculate concerning the antecedent and future conditions of things.

When we regard our globe with the mind's eye, it appears at the present time to be formed of concentric spheres, very like, and still very unlike, the successive coats of an onion. Within is situated the vast nucleus or *centrosphere;* surrounding this is what may be called the *tektosphere* (*τηκτός*, molten), a shell of materials in a state bordering on fusion, upon which rests and creeps the *lithosphere*. Then follow *hydrosphere* and *atmosphere*, with the included *biosphere* (*βίος*, life). To the interaction of these six geospheres, through energy derived from internal and external sources, may be referred all the existing superficial phenomena of the planet.

The vast interior of the planetary mass, although not under direct observation, is known, from the results of the astronomer and physicist, to have a mean density of 5·6, or twice that of ordinary surface rock. The substances brought within the reach of observation in veinstones, in lavas, and hypogene rocks—by the action of water as a solvent and sublimant—warrant the belief that the centrosphere is largely made up of metals and metalloids with imprisoned gases. It is admitted that the vast nucleus has a very high temperature, but so enormous is the pressure of the superincumbent crust that the melting point of the substances in the interior is believed to be raised to a higher value than the temperature there existing—the centrosphere in consequence remains solid, for it may be assumed that the melting point of rock-forming materials is raised by increase of pressure. Astronomers, from a study of precession and nutation, have long been convinced that the centrosphere must be practically solid.

Recent seismological observations indicate the transmission of two types of waves through the earth—the condensational-rarefactional and the purely distortional—and the study of these tremors supports the view that the centrosphere is not only solid, but possesses great uniformity of structure. The seismological investigations of Profs. Milne and Knott point also to a fairly abrupt boundary or transition surface, where the solid nucleus passes into the somewhat plastic magma on which the firm upper crust rests.

In this plastic layer or shell—named the *tektosphere*—the materials are most probably in a state of unstable equilibrium and bordering on fusion. Here the loose textured solids of the external crust are converted into the denser solids of the nucleus or into molten masses, at a critical point of temperature and pressure; deep-seated rocks may in consequence escape through fissures in the lithosphere. Within the lithosphere itself, the temperature falls off so rapidly towards the surface as to be everywhere below the melting point of any substance there under its particular pressure.

Now, as the solid centrosphere slowly contracted from loss of heat, the primitive lithosphere, in accommodating itself—through changes in the tektosphere—to the shrinking nucleus, would be buckled, warped, and thrown into ridges. That these movements are still going on is shown by the fact that the lithosphere is everywhere and at all times in a slight but measurable state of pulsation. The rigidity of the primitive rocky crust would permit of considerable deformations of the kind here indicated. Indeed, the compression of mountain chains has most probably been brought about in this manner, but the same cannot be said of the elevation of plateaus, of mountain platforms, and of continents.

From many lines of investigation it is concluded, as we have seen, that the centrosphere is homogeneous in structure. Direct observation, on the other hand, shows that the lithosphere is heterogeneous in composition. How has this heterogeneity been brought about? The original crust was almost certainly composed of complex and stable silicates, all the silicon dioxide being in combination with bases. Lord Kelvin has pointed out that, when the solid crust began to form, it would rapidly cool over its whole surface; the precipitation of water would accelerate this process, and there would soon be an approximation to present conditions. As time went on the plastic or critical layer—the tektosphere—immediately beneath the crust would gradually sink deeper and deeper, while ruptures and re-adjustments would become less and less frequent than in earlier stages. With the first fall of rain the silicates of the crust would be attacked by water and carbon dioxide, which can at low temperatures displace silicon dioxide from its combinations. The silicates, in consequence, have been continuously robbed of a part, or the whole of their bases. The silica thus set free goes ultimately to form quartz veins and quartz sand on or about the emerged land, while the bases leached out of the disintegrating rocks are carried out into the ocean and ocean-basins. A continuous disintegration and differentiation of materials of the lithosphere, accompanied by a sort of migration and selection among mineral substances, is thus always in progress. Through the agency of life, carbonate of lime accumulates

in one place; through the agency of winds, quartz sand is heaped up in another; through the agency of water, beds of clay, of oxides of iron and of manganese are spread out in other directions.

The contraction of the centrosphere supplies the force which folds and crumples the lithosphere. The combined effect of hydrosphere, atmosphere and biosphere on the lithosphere gives direction and a determinate mode of action to that force. From the earliest geological times the most resistant dust of the continents has been strewn along the marginal belt of the sea-floor skirting the land. At the present time, the deposits over this area contain on the average about 70 per cent. of free and combined silica, mostly in the form of quartz sand. In the abysmal deposits far from land there is an average of only about 30 per cent. of silica, and hardly any of this in the form of quartz sand. Lime, iron and the other bases largely predominate in these abysmal regions. The continuous loading on the margins of the emerged land by deposits tends by increased pressure to keep the materials of the tektosphere in a solid condition immediately beneath the loaded area. The unloading of emerged land tends by relief of pressure to produce a viscous condition of the tektosphere immediately beneath the denuded surfaces. Under the influence of the continuous shakings, tremors and tremblings always taking place in the lithosphere, the materials of the tektosphere yield to the stresses acting on them, and the deep-seated portions of the terrigenous deposits are slowly carried towards, over or underneath the emerged land. The rocks subsequently re-formed beneath continental areas out of these terrigenous materials, under great pressure and in hydrothermal conditions, would be more acid than the rocks from which they were originally derived, and it is well known that the acid silicates have a lower specific gravity than the intermediate or basic ones. By a continual repetition of this process the continental protuberances have been gradually built up of lighter materials than the other parts of the lithosphere. The relatively light quartz, which is also the most refractory, the most stable and the least fusible among rock-forming minerals, plays in all this the principal *rôle*. The average height of the surface of the continents is about three miles above the average level of the abysmal regions. If now we assume the average density of the crust beneath the continents to be 2·5, and of the part beneath the abysmal regions to be 3, then the spheroidal surface of equal pressure—the tektosphere—would have a minimum depth of eighteen miles beneath the continents and fifteen miles beneath the oceans, or if we assume the density of the crust beneath the continents to be 2·5, and beneath the abysmal regions to be 2·8, then the tektosphere would be twenty-eight miles beneath the continents and twenty-five miles beneath the oceans. The present condition of the earth's crust might be brought about by the disintegration of a quantity of quartz-free volcanic rock, covering the continental areas to a depth of eighteen miles, and the re-formation of rocks out of the disintegrated materials.

Where the lighter and more bulky substances have accumulated there has been a relative increase of volume, and in consequence bulging has taken place at the surface over the continental areas. Where the denser materials have been laid down there has been flattening, and in consequence a depression of the abysmal regions of the ocean-basins. It is known that, as a general rule, where large masses of sediment have been deposited, their deposition has been accompanied by a depression of the area. On the other hand, where broad mountain platforms have been subjected to extensive erosion, the loss of altitude by denudation has been made good by a rise of the platform. This points to a movement of matter on to the continental areas.

If this be anything like a true conception of the interactions that are taking place between the various geospheres of which our globe is made up, then we can understand why, in the gradual evolution of the surface features, the average level of the continental plains now stands permanently about three miles above the average level of those plains which form the floor of the deep ocean-basins. We may also understand how the defect of mass under continents and an excess of mass under the oceans have been brought about, as well as deficiency of mass under mountains and excess of mass under plains. Even the local anomalies indicated by the plumb-line, gravity and magnetic observations may in this way receive a rational explanation. It has been urged that an enormous time—greater even than what is demanded by Darwin—would be necessary for an evolution of the existing surface features on these lines. I do not think so. Indeed, in all that relates to geological time I agree, generally speaking, with the physicists rather than with the biologists and geologists.

### *Progress of Oceanic Research.*

I have now touched on some of the problems and speculations suggested by recent deep-sea explorations; and there are many others, equally attractive, to which no reference has been made. It is abundantly evident that, for the satisfactory explanation of many marine phenomena, further observations and explorations are necessary. Happily there is no sign that the interest in oceanographical work has in any way slackened. On the contrary, the number of scientific men and ships engaged in the study of the ocean is rapidly increasing. Among all civilised peoples and in all quarters of the globe the economic importance of many of the problems that await solution is clearly recognised.

We have every reason to be proud of the work continually carried on by the officers and ships attached to the Hydrographic Department of the British Navy. They have surveyed coasts in all parts of the world for the purposes of navigation, and within the past few years have greatly enlarged our knowledge of the sea-bed and deeper waters over wide stretches of the Pacific and other oceans. The samples of the bottom which are procured, being always carefully preserved by the officers, have enabled very definite notions to be formed as to the geographical and bathymetrical distribution of marine deposits.

The ships belonging to the various British telegraph cable companies have done most excellent work in this as well as in other directions. Even during the present year Mr. R. E. Peake has in the s.s. *Britannia* procured 477 deep soundings in the North Atlantic, besides a large collection of deep-sea deposits, and many deep-sea temperature and current observations.

The French have been extending the valuable work of the *Talisman* and *Travailleur*, while the Prince of Monaco is at the present moment carrying on his oceanic investigations in the Arctic Seas with a large new yacht elaborately and specially fitted out for such work. The Russians have recently been engaged in the scientific exploration of the Black Sea and the Caspian Sea, and a special ship is now employed in the investigation of the Arctic fisheries of the Murman coast under the direction of Prof. Knipowitsch. Admiral Makaroff has this summer been hammering his way through Arctic ice, and at the same time carrying on a great variety of systematic observations and experiments on board the *Yermak*—the most powerful and most effective instrument of marine research ever constructed. Mr. Alexander Agassiz has this year recommenced his deep-sea explorations in the Pacific on board the U.S. steamer *Albatross*. He proposes to cross the Pacific in several directions, and to conduct investigations among the Paumotu and other coral island groups. Prof. Weber is similarly employed on board a Dutch man-of-war in the East Indian Seas. The Deutsche Seewarte at Hamburg, under the direction of Dr. Neumayer, continues its praiseworthy assistance and encouragement to all investigators of the ocean, and this year the important German Deep-Sea Expedition, in the s.s. *Valdivia*, arrived home after most successful oceanographical explorations in the Atlantic, Indian and Great Southern Oceans.

The *Belgica* has returned to Europe safely with a wealth of geological and biological collections and physical observations, after spending, for the first time on record, a whole winter among the icefields and icebergs of the Antarctic. Mr. Borchgrevink in December last again penetrated to Cape Adare, successfully landed his party at that point and is now wintering on the Antarctic continent. The expeditions of Lieut. Peary, of Prof. Nathorst, of Captain Sverdrup, and of the Duke of Abruzzi, which are now in progress, may be expected to yield much new information about the condition of the Arctic Ocean. Mr. Wellman has just returned from the north of Franz Josef Land with observations of considerable interest.

Some of the scientific results obtained by the expeditions in the Danish steamer *Ingolf* have lately been published, and these, along with the results of the joint work pursued for many years by the Swedes, Danes and Norwegians, may ultimately have great economic value from their direct bearing on fishery problems and on weather forecasting over long periods of time.

Largely through the influence of Prof. Otto Pettersson, an International Conference assembled at Stockholm a few months ago, for the purpose of deliberating as to a programme of conjoint scientific work in the North Sea and northern parts of the Atlantic, with special reference to the economic aspect of sea-fisheries. A programme was successfully drawn up, and an organisation suggested for carrying it into effect: these proposals are now under the consideration of the several States. The Norwegian Government has voted a large sum of money for building a special vessel to conduct marine investigations of the nature recommended by this conference. It is to be hoped the other North Sea Powers may soon follow this excellent example.

The various marine stations and laboratories for scientific research in all parts of the world furnish each year much new knowledge concerning the ocean. Among our own people the excellent work carried on by the Marine Biological Association, the Irish Fisheries Department, the Scottish Fishery Board, the Lancashire Fisheries Committee, the Cape and Canadian Fisheries Departments, is well worthy of recognition and continued support. Mr. George Murray, Mr. H. N. Dickson, Prof. Cleve, Prof. Otto Pettersson, Mr. Robert Irvine and others have, with the assistance of the officers of the Mercantile Marine, accumulated in recent years a vast amount of information regarding the distribution of temperature and salinity, as well as of the planktonic organisms at the surface of the ocean. The papers by Mr. H. C. Russell on the icebergs and currents of the Great Southern Ocean, and of Mr. F. W. Walker on the density of the water in the Southern Hemisphere, show that the Australian Colonies are taking a practical interest in oceanographical problems.

*Proposed Antarctic Explorations.*

The great event of the year, from a geographical point of view, is the progress that has been made towards the realisation of a scheme for the thorough scientific exploration in the near future of the whole South Polar region. The British and German Governments have voted or guaranteed large sums of money to assist in promoting this object, and princely donations have likewise been received from private individuals, in this connection the action of Mr. L. W. Longstaff in making a gift of 25,000*l.*, and of Mr. A. C. Harmsworth in promising 5000*l.*, being beyond all praise.

There is an earnest desire among the scientific men of Britain and Germany that there should be some sort of co-operation with regard to the scientific work of the two expeditions, and that these should both sail in 1901, so that the invaluable gain attaching to simultaneous observations may be secured. Beyond this nothing has, as yet, been definitely settled. The members of the Association will presently have an opportunity of expressing their opinions as to what should be attempted by the British expedition, how the work in connection with it should be arranged, and how the various researches in view can best be carried to a successful issue.

I have long taken a deep interest in Antarctic exploration, because such exploration must necessarily deal largely with oceanographical problems, and also because I have had the privilege of studying the conditions of the ocean within both the Arctic and Antarctic circles. In the year 1886 I published an article on the subject of Antarctic Exploration in the *Scottish Geographical Magazine*. This article led to an interesting interview, especially when viewed in the light of after events, for, a few weeks after it appeared in type, a young Norwegian walked into the *Challenger* office in Edinburgh to ask when the proposed expedition would probably start, and if there were any chance of his services being accepted. His name was Nansen.

When at the request of the President I addressed the Royal Geographical Society on the same subject in the year 1893, I made the following statement as to what it seemed to me should be the general character of the proposed exploration: "A dash at the South Pole is not, however, what I advocate, nor do I believe *that* is what British science at the present time desires. It demands rather a steady, continuous, laborious and systematic exploration of the whole southern region with all the appliances of the modern investigator." At the same time I urged further, that these explorations should be undertaken by the Royal Navy in two ships, and that the work should extend over two winters and three summers.

This scheme must now be abandoned, so far at least as the Royal Navy is concerned, for the Government has intimated that it can spare neither ships nor officers, men nor money, for an undertaking of such magnitude. The example of Foreign Powers—rather than the representations from our own scientific men—appears to have been chiefly instrumental in at last inducing the Government to promise a sum of 45,000*l.*, provided that an equal amount be forthcoming from other sources. This resolve throws the responsibility for the financial administration, for the equipment and for the management of this exploration on the representative scientific societies, which have no organisation ready for carrying out important executive work on such an extensive scale. I am doubtful whether this state of matters should be regarded as a sign of increasing lukewarmness on the part of the Government towards marine research, or should rather be looked on as a most unexpected and welcome recognition of the growing importance of science and scientific men to the affairs of the nation. Let us adopt the latter view, and accept the heavy responsibility attached thereto.

Any one who will take the trouble to read, in the *Proceedings* of the Royal Society of London, the account of the discussion which recently took place on "The Scientific Advantages of an Antarctic Expedition," will gather some idea of the number and wide range of the subjects which it is urged should be investigated within the Antarctic area; the proposed researches have to do with almost every branch of science. Unless an earnest attempt be made to approach very near to the ideal there sketched out, widespread and lasting disappointment will certainly be felt among the scientific men of this country. The proposed expedition should not be one of adventure. Not a rapid invasion and a sudden retreat, with tales of hardships and risks, but a scientific occupation of the unknown area by observation and experiment should be aimed at in these days.

I have all along estimated the cost of a well-equipped Antarctic expedition at about 150,000*l.* I see no reason for changing my views on this point at the present time, nor on the general scope of the work to be undertaken by the proposed expedition, as set forth in the papers I have published on the subject. There is now a sum of at most 90,000*l.* in hand, or in view. If one ship should be specially built for penetrating the icy region, and be sent south with one naturalist on board, then such an expedition may, it will be granted, bring back interesting and important results. But it must be distinctly understood that this is not the kind of exploration scientific men have been urging on the British public for the past fifteen or twenty years. We must, if possible, have two ships, with landing parties for stations on shore, and with a recognised scientific leader and staff on board of each ship. Although we cannot have the Royal Navy, these ships can be most efficiently officered and manned from the Mercantile Marine. With only one ship many of the proposed observations would have to be cut out of the programme. In anticipation of this being the case, there are at the present moment irreconcilable differences of opinion among those most interested in these explorations, as to which sciences must be sacrificed.

The difficulties which at present surround this undertaking are fundamentally those of money. These difficulties would at once disappear, and others would certainly be overcome, should the members of the British Association at this meeting agree to place in the hands of their President a sum of 50,000*l.*, so that the total amount available for Antarctic exploration would become something like 150,000*l.* Although there is but one central Government, surely there are within the bounds of this great Empire two more men like Mr. Longstaff. The Government has suddenly placed the burden of upholding the high traditions of Great Britain in marine research and exploration on the shoulders of her scientific men. In their name I appeal to all our well-to-do fellow-countrymen in every walk of life for assistance, so that these new duties may be discharged in a manner worthy of the Empire and of the well-earned reputation of British Science.

## SECTION G.

### MECHANICAL SCIENCE.

OPENING ADDRESS BY SIR WILLIAM WHITE, K.C.B., LL.D., F.R.S., PRESIDENT OF THE SECTION.

IN this Address it is proposed to review briefly the characteristic features of the progress made in steam navigation; to glance at the principal causes of advance in the speeds of steamships and in the lengths of the voyages on which such vessels

can be successfully employed; and to indicate how the experience and achievement of the last sixty years bear upon the prospects of further advance.

There is reason to hope that this choice of subject is not inappropriate. From the beginning of steam navigation the British Association in its corporate capacity, by the appointment of special committees, and by the action of individual members, has greatly assisted the scientific treatment of steamship design. Valuable contributions bearing on the resistance offered by water to the motion of ships, the conduct and analysis of the results of steamship trials, the efficiency of propellers and cognate subjects have been published in the Reports of the Association. Many of these have largely influenced practice, and most of them may be claimed as the work of this Section.

On this occasion no attempt will be made either to summarise or appraise the work that has been done. It must suffice to mention the names of three men to whom naval architects are deeply indebted, and whose labours are ended—Scott Russell, Rankine, and William Froude. Each of them did good work, but to Froude we owe the device and application of the method of model experiment with ships and propellers, by means of which the design of vessels of novel types and unprecedented speeds can now be undertaken with greater confidence than heretofore.

As speeds increase, each succeeding step in the ascending scale becomes more difficult, and the rate of increase in the power to be developed rapidly augments. Looking back on what has been achieved, it is impossible to overrate the courage and skill displayed by the pioneers of steam navigation, who had at first to face the unknown, and always to depend almost entirely on experience gained with actual ships, when they undertook the production of swifter vessels. Their successors of the present day have equal need to make a thorough study of the performances of steamships both in smooth water and at sea. In many ways they have to face greater difficulties than their predecessors, as ships increase in size and speed. On the other hand, they have the accumulated experience of sixty years to draw upon, the benefit of improved methods of trials of steamships, the advantage of scientific procedure in the record and analysis of such trials and the assistance of model experiments.

Steamship design to be successful must always be based on experiment and experience as well as on scientific principles and processes. It involves problems of endless variety and great complexity. The services to be performed by steamships differ in character, and demand the production of many distinct types of ships and propelling apparatus. In all these types, however, there is one common requirement—the attainment of a specified speed. And in all types there has been a continuous demand for higher speed.

Stated broadly, the task set before the naval architect in the design of any steamship is to fulfil certain conditions of speed in a ship which shall not merely carry fuel sufficient to traverse a specified distance at that speed, but which shall carry a specified load on a limited draught of water. Speed, load, power and fuel supply are all related; the two last have to be determined in each case. In some instances other limiting conditions are imposed affecting length, breadth or depth. In all cases there are three separate efficiencies to be considered: those of the ship as influenced by her form; of the propelling apparatus, including the generation of steam in the boilers and its utilisation in the engines; and of the propellers. Besides these considerations, the designer has to take account of the materials and structural arrangements which will best secure the association of lightness with strength in the hull of the vessel. He must select those types of engines and boilers best adapted for the service proposed. Here the choice must be influenced by the length of the voyage, as well as the exposure it may involve to storm and stress. Obviously the conditions to be fulfilled in an ocean-going passenger steamer of the highest speed, and in a cross-Channel steamer designed to make short runs at high speed in comparatively sheltered waters, must be radically different. And so must be the conditions in a swift sea-going cruiser of large size and great coal endurance, from those best adapted for a torpedo boat or destroyer. There is, in fact, no general rule applicable to all classes of steamships: each must be considered and dealt with independently, in the light of the latest experience and improvements. For merchant ships there is always the commercial consideration—Will it pay? For warships there is the corresponding inquiry—Will the cost be justified by the fighting power and efficiency?

*Characteristics of Progress in Steam Navigation.*

Looking at the results so far attained, it may be said that progress in steam navigation has been marked by the following characteristics:—

(1) Growth in dimensions and weights of ships, and large increase in engine-power, as speeds have been raised.

(2) Improvements in marine engineering accompanying increase of steam pressure. Economy of fuel and reduction in the weight of propelling apparatus in proportion to the power developed.

(3) Improvements in the materials used in shipbuilding; better structural arrangements; relatively lighter hulls and larger carrying power.

(4) Improvements in form, leading to diminished resistance and economy of power expended in propulsion.

These general statements represent well-known facts—so familiar, indeed, that their full significance is often overlooked. It would be easy to multiply illustrations, but only a few representative cases will be taken.

*Transatlantic Passenger Steamers.*

The Transatlantic service naturally comes first. It is a simple case, in that the distance to be covered has remained practically the same, and that for most of the swift passenger steamers cargo-carrying capacity is not a very important factor in the design.

In 1840 the Cunard steamship *Britannia*, built of wood, propelled by paddle-wheels, maintained a sea-speed of about 8½ knots. Her steam pressure was 12 lbs. per square inch. She was 207 feet long, about 2000 tons in displacement, her engines developed about 750 horse-power, and her coal consumption was about 40 tons per day, nearly 5 lbs. of coal per indicated horse-power per hour. She had a full spread of sail.

In 1871 the White Star steamship *Oceanic* (first of that name) occupied a leading position. She was iron-built, propelled by a screw, and maintained a sea-speed of about 14½ knots. The steam pressure was 65 lbs. per square inch, and the engines were on the compound principle. She was 420 feet long, about 7200 tons in displacement, her engines developed 3000 horse-power, and she burnt about 65 tons of coal per day, or about 2 lbs. per indicated horse-power per hour. She carried a considerable spread of sail.

In 1889 the White Star steamer *Teutonic* appeared, propelled by twin screws and practically with no sail-power. She is steel-built, and maintains a sea-speed of about 20 knots. The steam pressure is 180 lbs. per square inch, and the engines are on the triple expansion principle. She is about 565 feet long, 16,000 tons displacement, 17,000 horse-power indicated, with a coal consumption of about 300 tons a day, or from 1·6 to 1·7 lbs. per indicated horse-power per hour.

In 1894 the Cunard steamship *Campania* began her service, with triple expansion engines, twin screws and no sail-power. She is about 600 feet long, 20,000 tons displacement, develops about 28,000 horse-power at full speed of 22 knots, and burns about 500 tons of coal per day.

The new *Oceanic*, of the White Star Line, is just beginning her work. She is of still larger dimensions, being 685 feet in length and over 25,000 tons displacement. From the authoritative statements made, it appears that she is not intended to exceed 22 knots in speed, and that the increase in size is to be largely utilised in additional carrying power.

The latest German steamers for the Transatlantic service are also notable. A speed of 22½ knots has been maintained by the *Kaiser Wilhelm der Grosse*, which is 25 feet longer than the *Campania*. Two still larger steamers are now building. The *Deutschland* is 660 feet long and 23,000 tons displacement; her engines are to be of 33,000 horse-power, and it is estimated she will average 23 knots. The other vessel is said to be 700 feet long, and her engines are to develop 36,000 horse-power, giving an estimated speed of 23½ knots. All these vessels have steel hulls and twin screws. It will be noted that to gain about three knots an hour nearly 50 per cent. will have been added to the displacement of the *Teutonic*, the engine-power and coal consumption will be doubled, and the cost increased proportionately.

Sixty years of continuous effort and strenuous competition on this great "ocean ferry" may be summarised in the following statement. Speed has been increased from 8½ to 22½ knots; the time on the voyage has been reduced to about 38 per cent.

of what it was in 1840. Ships have been more than trebled in length, about doubled in breadth, and increased tenfold in displacement. The number of passengers carried by a steamship has been increased from about 100 to nearly 2000. The engine-power has been made forty times as great. The ratio of horse-power to the weight driven has been increased fourfold. The rate of coal consumption (measured per horse-power per hour) is now only about one-third what it was in 1840. To drive 2000 tons weight across the Atlantic at a speed of $8\frac{1}{2}$ knots, about 550 tons of coal were then burnt: now, to drive 20,000 tons across at 22 knots, about 3000 tons of coal are burnt. With the low pressure of steam and heavy slow-moving paddle-engines of 1840, each ton weight of machinery, boilers, &c., produced only about 2 horse-power for continuous working at sea. With modern twin-screw engines and high steam pressure, each ton weight of propelling apparatus produces from 6 to 7 horse-power. Had the old rate of coal consumption continued, instead of 3000 tons of coal, 9000 tons would have been required for a voyage at 22 knots. Had the engines been proportionately as heavy as those in use sixty years ago, they would have weighed about 14,000 tons. In other words, machinery, boilers, and coals would have exceeded in weight the total weight of the *Campania* as she floats to-day. There could not be a more striking illustration than this of the close relation between improvements in marine engineering and the development of steam navigation at high speeds.

Equally true is it that this development could not have been accomplished but for the use of improved materials and structural arrangements. Wood, as the principal material for the hulls of high-powered swift steamers, imposed limits upon dimensions, proportions and powers which would have been a bar to progress. The use of iron, and later of steel, removed those limits. The percentage of the total displacement devoted to hull in a modern Atlantic liner of the largest size is not much greater than was the corresponding percentage in the wood-built *Britannia* of 1840, of one-third the length and one-tenth the total weight.

Nor must it be overlooked that with increase in dimensions have come considerable improvements in *form*, favouring economy in propulsion. This is distinct from the economy resulting from increase in *size*, which Brunel appreciated thoroughly half a century ago when he designed the *Great Britain* and the *Great Eastern*. The importance of a due relation between the lengths of the "entrance and run" of steamships and their intended maximum speeds, and the advantages of greater length and fineness of form as speeds are increased, were strongly insisted upon by Scott Russell and Froude. Naval architects, as a matter of course, now act upon the principle, so far as other conditions permit. For it must never be forgotten that economy of propulsion is only one of many desiderata which must be kept in view in steamship design. Structural weight and strength, seaworthiness and stability, all claim attention, and may necessitate modifications in dimensions and form which do not favour the maximum economy of propulsion.

### *Swift Passenger Steamers for Long Voyages.*

Changes similar to those described for the Transatlantic service have been in progress on all the great lines of ocean traffic. In many instances increase in size has been due, not only to increase in speed, but to enlarged carrying power and the extension of the lengths of voyages. No distance is now found too great for the successful working of steamships, and the sailing fleet is rapidly diminishing in importance. So far as long-distance steaming is concerned, the most potent factor has undoubtedly been the marvellous economy of fuel that has resulted from higher steam pressures and greater expansion. In all cases, however, advances have been made possible, not merely by economy of fuel, but by improvements in form, structure and propelling apparatus, and by increased dimensions.

Did time permit, this might be illustrated by many interesting facts drawn from the records of the great steamship companies which perform the services to the Far East, Australia, South America, and the Pacific. As this is not possible, I must be content with a brief statement regarding the development of the fleet of the Peninsular and Oriental Company.

The paddle steamer *William Fawcett* of 1829 was about 75 feet long, 200 tons displacement, of 60 nominal horse-power (probably about 120 indicated horse-power), and in favourable weather steamed at a speed of 8 knots. Her hul was of wood, and, like all the steamers of that date, she had considerable sail-power.

In 1853 the *Himalaya* iron-built screw steamer of this line was described as "of larger dimensions than any then afloat, and of extraordinary speed." She was about 340 feet long, over 4000 tons load displacement, 2000 indicated horse-power on trial, with an average sea-speed of about 12 knots. The steam pressure was 14 lbs. per square inch, and the daily coal consumption about 70 tons. This vessel was transferred to the Royal Navy and did good service as a troopship for forty years.

In 1893 another *Himalaya* was added to the company's fleet. She was steel-built, nearly 470 feet long and 12,000 tons load displacement, with over 8000 indicated horse-power and a capability to sustain 17 to 18 knots at sea, on a daily consumption of about 140 tons of coal. The steam pressure is 160 lbs. per square inch, and the engines are of the triple expansion type.

Comparing the two *Himayalas*, it will be seen that in forty years the length has been increased about 40 per cent., displacement trebled, horse-power quadrupled and speed increased about 50 per cent. The proportion of horse-power to displacement has only been increased as three to four, enlarged dimensions having secured relative economy in propulsion. The rate of coal consumption has been probably reduced to about one-third of that in the earlier ship

The latest steamers of the line are of still larger dimensions, being 500 feet long and of proportionately greater displacement. It is stated that the *Himalaya* of 1853 cost 132,000*l.* complete for sea: the corresponding outlay on her successors is not published, but it is probably twice as great.

On the service to the Cape similar developments have taken place. Forty years ago vessels less than 200 feet long and about 7 knots performed the service, whereas the latest additions to the fleets exceed 500 feet in length, and can, if required, be driven at 17 to 18 knots, ranking in size and power next to the great Transantlaotic liners.

Commercial considerations necessarily regulate what is undertaken in the construction of merchant steamers, including the swift vessels employed in the conveyance of passengers and mails. The investment of 600,000*l.* to 700,000*l.* in a single vessel like a great Transatlantic liner is obviously a serious matter for private owners; and even the investment of half that amount in a steamer of less dimensions and speed is not to be lightly undertaken. It is a significant fact that, whereas fifteen years ago nearly all the largest and swiftest ocean steamers were British built and owned, at the present time there is serious competition in this class by German, American and French companies. It is alleged that this change has resulted from the relatively large subsidies paid by foreign Governments to the owners of swift steamers; and that British owners, being handicapped in this way, cannot continue the competition in size and speed on equal terms unless similarly assisted. This is not the place to enter into any discussion of such matters, but they obviously involve greater considerations than the profit of shipowners, and have a bearing on the naval defence of the Empire. In 1887 the Government recognised this fact, and made arrangements for the subvention and armament of a number of the best mercantile steamships for use as auxiliary cruisers. Since then other nations have adopted the policy, and given such encouragement to their shipowners that the numbers of swift steamers suitable for employment as cruisers have been largely increased. Not long since the First Lord of the Admiralty announced to Parliament that the whole subject was again under consideration.

### *Cargo and Passenger Steamers.*

Cargo steamers, no less than passenger steamers, have been affected by the improvements mentioned. Remarkable developments have occurred recently, not merely in the purely cargo-carrier, but in the construction of vessels of large size and good speed carrying very great weights of cargo and considerable numbers of passengers. The much-decried "ocean-tramp" of the present day exceeds in speed the passenger and mail steamer of fifty years ago. Within ten years vessels in which cargo-carrying is the chief element of commercial success have been increased in length from 300 or 400 feet to 500 or 600 feet; in gross register tonnage from 5000 to over 13,000 tons; and in speed from 10 or 12 knots to 15 or 16 knots. Vessels are now building for the Atlantic service which can carry 12,000 to 13,000 tons deadweight, in addition

to passengers, while possessing a sea-speed as high as that of the swiftest mail steamers afloat in 1880. Other vessels of large carrying power and good speed are running on much longer voyages, such as to the Cape and Australia. In order to work these ships successfully very complete organisation is necessary for the collection, embarkation and discharge of cargo. The enterprise and skill of shipowners have proved equal to this new departure, as they have in all other developments of steamships.

How much further progress will be made in the sizes and speeds of these mixed cargo and passenger steamers cannot be foreseen. The limits will be fixed by commercial considerations, and not by the capability of the shipbuilder.

In passing, it may be noted that while the lengths and breadths of steamships have been greatly increased, there has been but a moderate increase in draught. Draught of water is, of course, practically determined by the depths available in the ports and docks frequented, or in the Suez Canal for vessels trading to the East. From the naval architect's point of view, increase in draught is most desirable as favouring increase of carrying power and economy of propulsion. This fact has been strongly represented by shipowners and ship-designers, and not without result. The responsible authorities of many of the principal ports and of the Suez Canal have taken action towards giving greater depth.

Other changes have become necessary on the part of dock and port authorities in consequence of the progress made in shipbuilding. Docks and dock-entrances have had to be increased in size, more powerful lifting appliances provided and large expenditure incurred. There is no escape from these changes if the trade of a port is to be maintained. The chief lesson to be learnt from past experience is that when works of this character are planned it is wise to provide a large margin beyond the requirements of existing ships.

*Cross-Channel Steamers.*

The conditions to be fulfilled in vessels designed to steam at high speed for limited periods differ essentially from those holding good in ocean-going steamers. None the less interest attaches, however, to cross-Channel steamers, and in no class has more notable progress been made. It is much to be desired that at this meeting some competent authority should have presented to the Association an epitome of the history of the steam packet service between Dover and the continent. I cannot attempt it. So far as I am informed, the first steamer was placed on this route in 1821, was of 90 tons burden, 30 horse-power nominal, and maintained a speed of 7 to 8 knots. She was built by Denny of Dumbarton, engined by David Napier and named the *Rob Roy*. It is interesting to note that the lineal successors of the builder of this pioneer vessel have produced some of the most recent and swiftest additions to the cross-Channel service.

In 1861–2 a notable advance was made by the building of vessels which were then remarkable for structure and speed, although small and slow when compared with vessels now running. Their designers realised that lightness of hull was of supreme importance, and with great trouble and expense obtained steel of suitable quality. The machinery was of special design and relatively light for the power developed. A small weight of coal and cargo had to be carried, and the draught of water was kept to about 7 feet. Under then existing conditions it was a veritable triumph to attain speeds of 15 to 16 knots in vessels only 190 feet long, less than 25 feet broad, and under 350 tons in displacement. To raise the trial speed to 20 or 21 knots in later vessels performing the same service, whose design includes the improvements of a quarter of a century, it has been found necessary to adopt lengths exceeding 320 feet and breadths of about 35 feet, with engines developing 4500 to 6000 indicated horse-power, and with very great increase in coal consumption and cost. On other cross-Channel services between Dover and the continent still larger and more powerful paddle-steamers are employed.

Another interesting contrast is to be found in the comparison of the steamers running between Holyhead and Kingstown in 1860 and at the present time. The *Leinster* of 1860 was 328 feet long, 35 feet broad and rather less than 13 feet draught. Her trial displacement was under 2000 tons and with 4750 horse-power she made $17\frac{3}{4}$ knots. She had a steam pressure of 25 lbs. per square inch and was propelled by paddle-wheels driven by slow-moving engines of long stroke. Her successor of 1896 is about 30 feet greater length, $6\frac{1}{2}$ feet greater breadth and about 10 per cent. greater displacement. The steam pressure is 170 lbs. per square inch. Forced draught is used in the stokeholds. Twin screws are adopted, driven by quick-running vertical engines of the triple expansion type. Very great economy of coal consumption is thus secured as compared with the earlier vessel, and much lighter propelling apparatus in proportion to the power, which is from 8000 to 9000 horse-power at the full speed of 23 knots. The hull is built of steel, and is proportionately lighter.

This is a typical case, and illustrates the effect of improvements in shipbuilding and engineering in thirty-five years. The later ship probably requires to carry no greater load of coal than, if so great as, her predecessor, although her engine-power is nearly double. The weight devoted to propelling machinery and boilers is probably not so great. Thanks to the use of steel instead of iron, and to improved structural arrangements, the weight of hull is reduced in comparison with dimensions, and a longer ship is produced better adapted to the higher speed. Messrs. Laird of Birkenhead, who built three of the *Leinster* class forty years ago, and have built all the new vessels, are to be congratulated on their complete success.

Between such vessels designed for short runs at high speed and requiring therefore to carry little coal, while the load carried exclusive of coal is trifling, and an ocean-going steamer of the same average speed designed to make passages of 3000 miles, there can obviously be little in common. But equal technical skill is required to secure the efficient performance of both services. In the cross-Channel vessel, running from port to port, and under constant observation, conditions of working in engine and boiler rooms, as well as relative lightness in scantlings of hull, can be accepted which would be impossible of application in a sea-going ship. These circumstances in association with the small load carried explain the apparent gain in speed of the smaller vessel in relation to her dimensions.

*Increase in Size and Speed of Warships.*

Turning from sea-going ships of the mercantile marine to warships, one finds equally notable facts in regard to increase in speed, associated with enlargement in dimensions and advance in propelling apparatus, materials of construction, structural arrangements and form.

Up to 1860 a measured-mile speed of 12 to 13 knots was considered sufficient for battleships and the largest classes of cruisers. All these vessels possessed good sail-power and used it freely as an auxiliary to steam, or as an alternative when cruising or making passages.

When armoured battleships were built (1859) the speeds on measured-mile trials were raised to 14 or $14\frac{1}{2}$ knots, and so remained for about twenty years. Since 1880 the speeds of battleships have been gradually increased, and in the latest types the measured-mile speed required is 19 knots.

Up to 1870 the corresponding speeds in cruisers ranged from 15 to 16 knots. Ten years later the maximum speeds were 18 to $18\frac{1}{2}$ knots in a few vessels. Since then trial speeds of 20 to 23 knots have been attained or are contemplated.

There is, of course, a radical distinction between these measured-mile performances of warships and the average sea-speeds of merchant steamers above described. But for purposes of comparison between warships of different dates, measured mile trials may fairly be taken as the standard. For long-distance steaming the power developed would necessarily be much below that obtained for short periods and with everything at its best. This is frankly recognised by all who are conversant with the warship design, and fully allowed for in estimates of sea-speeds. On the other hand, it is possible to point to sea trials made with recent types where relatively high speeds have been maintained for long periods. For example, the battleship *Royal Sovereign* has maintained an average speed of 15 knots from Plymouth to Gibraltar, and the *Renown* has maintained an equal speed from Bermuda to Spithead. As instances of good steaming by cruisers, reference may be made to 60-hour trials with the *Terrible* when she averaged over 20 knots, and to the run home from Gibraltar to the Nore by the *Diadem* when she exceeded 19 knots. Vessels of the *Pelorus* class of only 2100 tons displacement have made long runs at sea averaging over 17 knots. Results such as these represent a substantial advance in speed of Her Majesty's ships in recent years.

Similar progress has been made in foreign warships built abroad as well as in this country. It is not proposed to give

any facts for these vessels, or to compare them with results obtained by similar classes of ships in the Royal Navy. Apart from full knowledge of the conditions under which speed trials are made, a mere statement of speeds attained is of no service. One requires to be informed accurately respecting the duration of the trial, the manner in which engines and boilers are worked, the extent to which boilers are "forced," or the proportion of heating surface to power indicated, the care taken to eliminate the influence of tide or current, the mode in which the observations of speed are made, and other details, before any fair or exact comparison is possible between ships. For present purposes, therefore, it is preferable to confine the illustrations of increase in speed in warships to results obtained under Admiralty conditions, and which are fairly comparable.

A great increase in size has accompanied this increase in speed, but it has resulted from other changes in modern types, as well as from the rise in speed. Modern battleships are of 13,000 to 15,000 tons, and modern cruisers of 10,000 to 14,000 tons, not merely because they are faster than their predecessors, but because they have greater powers of offence and defence and possess greater coal endurance. Only a detailed analysis, which cannot now be attempted, could show what is the actual influence of these several changes upon size and cost, and how greatly the improvements made in marine engineering and shipbuilding have tended to keep down the growth in dimensions consequent on increase in load carried, speed attained, and distance traversed.

It will be noted also that, large as are the dimensions of many classes of modern warships, they are all smaller in length and displacement than the largest mercantile steamers above described. There is no doubt a popular belief that the contrary is true, and that warships exceed merchant ships in tonnage. This arises from the fact that merchant ships are ordinarily described, not by their displacement tonnage, but by their "registered tonnage," which is far less than their displacement. As a matter of fact, the largest battleships are only of about two-thirds the displacement of the largest passenger steamers, and from 200 to 300 feet shorter. The largest cruisers are from 100 to 200 feet shorter than the largest passenger steamers, and about 60 per cent. of their displacement. In breadth the warships exceed the largest merchant steamers by 5 to 10 feet. This difference in form and proportions is the result of radical differences in the vertical distribution of weights carried, and is essential to the proper stability of the warships. Here we find an illustration of the general principle underlying all ship-designing. In selecting the forms and proportions of a new ship, considerations of economical propulsion cannot stand alone. They must be associated with other considerations, such as stability, protection and manœuvring power, and in the final result economy of propulsion may have to be sacrificed, to some extent, in order to secure other essential qualities.

### *Advantages of Increased Dimensions.*

Before passing on, it may be interesting to illustrate the gain in economy of propulsion resulting from increase in dimensions by means of the following table, which gives particulars of a number of typical cruisers, all of comparatively recent design :

| — | No. 1 | No. 2 | No. 3 | No. 4 | No. 5 |
|---|---|---|---|---|---|
| Length (feet) ... .. | 280 | 300 | 360 | 435 | 500 |
| Breadth (feet) ... ... | 35 | 43 | 60 | 69 | 71 |
| Mean draught (feet) ... | 13 | 16½ | 23¾ | 24½ | 26¼ |
| Displacement (tons) .. | 1800 | 3400 | 7,400 | 11,000 | 14,200 |
| Indicated horse-power for 20 knots .. ... . | 6000 | 9000 | 11,000 | 14,000 | 15,500 |
| Indicated horse-power per ton of displacement ... | 3·33 | 2·65 | 1·48 | 1·27 | 1·09 |

The figures given are the results of actual trials, and embody therefore the efficiencies of propelling machinery, propellers and forms of the individual ships. Even so they are instructive. Comparing the first and last, for example, it will be seen that, while the displacement is increased nearly *eightfold*, the power for 20 knots is only increased about 2·6 times. If the same types of engines and boilers had been adopted in these two vessels—which was not the case, of course—the weights of propelling apparatus and coal for a given distance would have been proportional to the respective powers ; that is to say, the larger vessel would have been equipped with only 2·6 times the weight carried by the smaller. On the other hand, roughly speaking, the *disposable weights*, after providing for hulls and fittings in these two vessels, might be considered to be proportional to their displacements. As a matter of fact, this assumption is distinctly in favour of the smaller ship. Adopting it, the larger vessel would have about *eight* times the disposable weight of the smaller ; while the demand for propelling apparatus and fuel would be only *2·6 times* that of the smaller vessel. There would therefore be an enormous margin of carrying power in comparison with displacement in the larger vessel. This might be devoted, and in fact was devoted, partly to the attainment of a speed considerably exceeding 20 knots (which was a maximum for the smaller vessel), partly to increased coal endurance and partly to protection and armament.

Another interesting comparison may be made between vessels Nos. 4 and 5 in the preceding table, by tracing the growth in power necessary to drive the vessels at speeds ranging from 10 knots up to 22 knots.

| | No. 4 | No. 5 |
|---|---|---|
| 10 knots ... | 1,500-horse-power | 1,800-horse-power |
| 12 ,, ... | 2,500 ,, ,, | 3,100 ,, ,, |
| 14 ,, ... | 4.000 ,, ,, | 5,000 ,, ,, |
| 16 ,, ... | 6,000 ,, ,, | 7,500 ,, ,, |
| 18 ,, ... | 9,000 ,, ,, | 11,000 ,, ,, |
| 20 ,, ... | 14,000 ,, ,, | 15,500 ,, ,, |
| 22 ,, ... | 23,000 ,, ,, | 23,000 ,, ,, |

It will be noted that up to the speed of 18 knots there is a fairly constant ratio between the powers required to drive the two ships. As the speeds are increased the larger ship gains, and at 22 knots the same power is required in both ships. The smaller vessel, as a matter of fact, was designed for a maximum speed of 20½ knots, and the larger for 22 knots. Unless other qualities had been sacrificed, neither space nor weight could have been found in the smaller vessel for machinery and coals corresponding to 22 knots. The figures are interesting, however, as illustrations of the principle that economy of propulsion is favoured by increase in dimensions as speeds are raised.

Going a step further, it may be assumed that in unsheathed cruisers of this class about 40 per cent. of the displacement will be required for the hull and fittings, so that the balance or "disposable weight" would be about 60 per cent. ; say 6600 tons for the smaller vessel, and 8500 tons for the larger, a gain of nearly 2000 tons for the latter. If the speed of 22 knots were secured in both ships, with machinery and boilers of the same type, the larger ship would therefore have about 2000 tons greater weight available for coals, armament, armour and equipment.

These illustrations of well-known principles have been given simply for the assistance of those not familiar with the subject, and they need not be carried further. More general treatment of the subject, based on experimental and theoretical investigation, will be found in text-books of naval architecture, but would be out of place in this Address.

### *Swift Torpedo Vessels.*

Torpedo flotillas are comparatively recent additions to war fleets. The first torpedo boat was built by Mr. Thornycroft for the Norwegian Navy in 1873, and the same gentleman built the first torpedo boat for the Royal Navy in 1877. The construction of the larger class, known as "torpedo-boat destroyers," dates from 1893. These various classes furnish some of the most notable examples extant of the attainment of extraordinarily high speeds, for short periods and in smooth water, by vessels of small dimensions. Their qualities and performances, therefore, merit examination.

Mr. Thornycroft may justly be considered the pioneer in this class of work. Greatly impressed by the combination of lightness and power embodied in railway locomotives, Mr. Thornycroft applied similar principles to the propulsion of small boats, and obtained remarkably high speeds. His work became more widely known when the results were published of a series of trials conducted in 1872 by Sir Frederick Bramwell on a small

vessel named the *Miranda*. She was only 45 feet long and weighed 4 tons, yet she exceeded 16 knots on trial. The Norwegian torpedo boat built in 1873 was 57 feet long, $7\frac{1}{2}$ tons, and of 15 knots; the first English torpedo boat of 1877 was 81 feet long, 29 tons and attained $18\frac{1}{2}$ knots.

Mr. Yarrow also undertook the construction of small swift vessels at a very early date, and has greatly distinguished himself throughout the development of the torpedo flotilla. Messrs. White, of Cowes, previously well known as builders of steamboats for use on board ships, extended their operations to the construction of torpedo boats. These three firms for a considerable time practically monopolised this special class of work in this country. Abroad they had able competitors in Normand in France, Schichau in Germany, and Herreshoff in the United States. Keen competition led to successive improvements and rapid rise in speed. During the last six years the demand for a fleet of about 100 destroyers, to be built in the shortest possible time, involved the necessity for increasing the sources of supply. At the invitation of the Admiralty, a considerable number of the leading shipbuilding and engineering firms have undertaken and successfully carried through the construction of destroyers varying from 26 to 33 knots in speed, although the work was necessarily of a novel character, involving many difficulties.

As the speeds of torpedo vessels have risen, so have their dimensions increased. Within the class the law shown to hold good in larger vessels applies equally. In 1877 a first-class torpedo boat was 81 feet long, under 30 tons weight, developed 400-horse-power, and steamed $18\frac{1}{2}$ knots. Ten years later the corresponding class of boat was 135 feet long, 125 tons weight, developed 1500 horse-power and steamed 23 knots. In 1897 it had grown to 150 feet in length, 140 to 150 tons, 2000 horse-power and 26 knots.

Destroyers are not yet of seven years' standing, but they come under the rule. The first examples (1893) were 180 feet long, 240 tons, 4000 horse-power and 26 to 27 knots. They were followed by 30-knot vessels, 200 to 210 feet long, 280 to 300 tons, 5500 to 6000 horse-power. Vessels now in construction are to attain 32 to 33 knots, their lengths being about 230 feet, displacements 360 to 380 tons and engine-power 8000 to 10,000 horse-power.

Cost has gone up with size and power, and the limit of progress in this direction will probably be fixed by financial considerations, rather than by constructive difficulties, great as these become as speeds rise.

It may be interesting to summarise the distinctive features of torpedo-vessel design.

(1) The propelling apparatus is excessively light in proportion to the maximum power developed. Water-tube boilers are now universally adopted, and on speed trials they are "forced" to a considerable extent. High steam pressures are used. The engines are run at a high rate of revolution—often at 400 revolutions per minute. Great care is taken in every detail to economise weight. Speed trials at maximum power only extend over three hours. On such trials in a destroyer each ton weight of propelling apparatus produces about 45 indicated horse-power. Some idea of the relative lightness of the destroyer's machinery and boilers will be obtained when it is stated that in a large modern cruiser with water-tube boilers, high steam pressure, and quick-running engines, the maximum power obtained on an eight hours' trial corresponds to about 12 indicated horse-power per ton of engines, boilers, &c. That is to say, the proportion of power to weight of propelling apparatus is from three and a half to four times as great in the destroyer as it is in the cruiser.

(2) A very large percentage of the total weight (or displacement) of a torpedo vessel is assigned to propelling apparatus. In a destroyer of 30 knots trial-speed, nearly one-half the total weight is devoted to machinery, boilers, &c. In the swiftest cruisers of large size the corresponding allocation of weight is less than 20 per cent. of the displacement, and in the largest and fastest mail steamers it is about 20 to 25 per cent.

(3) The torpedo vessel carries a relatively small load of fuel, equipment, &c. Taking a 30-knot destroyer, for example, the speed trials are made with a load not exceeding 12 to 14 per cent. of the displacement. In a swift cruiser the corresponding load would be from 40 to 45 per cent., or proportionately more than three times as great. What this difference means may be illustrated by two statements. If the load in a destroyer were trebled and the vessel correspondingly increased in draught and weight, the speed attained with the same maximum power would be about three knots less. If, on the other hand, the vessel were designed to attain 30 knots on trial with the heavier load, her displacement would probably be increased about 70 to 80 per cent.

(4) The hull and fittings of the torpedo vessel are exceedingly light in relation to the dimensions and engine-power. For many parts of the structure steel of high-tensile strength is used. Throughout, the utmost care is taken to economise weight. In small vessels, for special service, many conditions can be accepted which would be inadmissible in larger sea-going vessels. The result of all this care is the production of hull-structures having ample *general* strength for their special service. Lightness of scantling, of course, involves small *local* strength against collision, grounding and other accident. Experience proves, however, that this involves no serious risk or difficulty.

These conditions are essential to the attainment of very high speeds for short periods. They resemble the conditions ruling the design of cross-Channel steamers, so far as relative lightness of propelling apparatus, small load and light scantlings are concerned. The essential differences lie in the requirements for passenger accommodation as compared with the requirements for armament of the torpedo vessel. No one has yet proposed to extend the torpedo-vessel system to sea-going ships of large dimensions. Very similar conditions for the propelling apparatus have been accepted in a few cruisers of considerable dimensions, wherein high speeds for short periods were required. It is, however, unquestionable that in many ways, and particularly in regard to machinery design, the construction of torpedo vessels has greatly influenced that of larger ships.

One important consideration must not be overlooked. For short-distance steaming at high speeds economy in coal consumption is of little practical importance, and it is all-important to secure lightness of propelling apparatus in relation to power. For long-distance steaming, on the contrary, economy in coal consumption is of primary importance; and savings in weight of propelling apparatus, even of considerable amount, may be undesirable if they involve increased coal consumption. Differences of opinion prevail as to the real economy of fuel obtainable with boilers and engines such as are fitted in torpedo vessels. Claims are made for some vessels which represent remarkable economy. Only enlarged experience can settle these questions.

Endurance is also an important quality in sea-going ships of large size, not merely in structures, but in propelling apparatus. The extreme lightness essential in torpedo vessels obviously does not favour endurance if high powers are frequently or continuously required. Still, it cannot be denied that the results obtained in torpedo vessels show such a wide departure from those usual in sea-going ships as to suggest the possibility of some intermediate type of propelling apparatus applicable to large sea-going ships and securing sufficient durability and economy of fuel in association with further savings of weight.

### *The Parsons Turbo-Motor.*

The steam turbo-motor introduced by Mr. Charles Parsons is to be described by the inventor during these meetings; but it is impossible for me to pass it over in this review without a brief notice. This rotary engine, with its very high rate of revolution, reduces the weights of machinery, shafting and propellers greatly below the weight required in the quickest-running engines of the reciprocating type. This reduction in the proportion of weight to power carries with it, of course, the possibility of higher speed in a vessel of given dimensions; and when large powers are employed the absolute gain is very great. An illustration of this has been given by Mr. Parsons in the *Turbinia*. That remarkable vessel is 100 feet long and of $44\frac{1}{2}$ tons displacement, but she has attained 33 to 34 knots in short runs. There are three shafts, each carrying three screw propellers, each shaft driven by a steam turbine making over 2000 revolutions at full speed, when more than 2000-horse-power is developed. A water-tube boiler of special design supplies steam of 175 lbs. pressure, and is exceptionally light for the steam produced, being highly forced. The whole weight of machinery and boilers is 22 tons; in other words, about 100 horse-power (indicated) is produced for each ton weight of propelling apparatus. This is rather more than twice the proportion of power to weight as compared with the lightest machinery and boilers fitted in torpedo boats and destroyers. It will be noted that in the *Turbinia*, as in the destroyers, about half the total weight is devoted to propelling apparatus; and in both instances the load carried is relatively small. The secret

of the extraordinary speed is to be found in the extreme lightness of propelling apparatus and small load.

No doubt in the *Turbinia* lightness has been pushed further than it would be in vessels of larger size and greater power. In such vessels a lower rate of revolution would probably be accepted, additional motors would be fitted for manœuvring and going astern, boilers of relatively greater weight would be adopted and other changes made. But, after making ample allowance for all such increases in weight, it is unquestionable that considerable economies must be possible with rotary engines. Two other vessels of the destroyer type with turbo-motors (one for the Royal Navy) are now approaching completion. Their trials will be of great interest, as they will furnish a direct comparison with vessels of similar size and form, fitted with similar boilers and driven by reciprocating engines.

On the side of coal consumption, Mr. Parsons claims at least equality with the best triple expansion engines. Into the other advantages attending the use of rotary engines it is not necessary now to enter.

Reference must be made, however, to one matter in which Mr. Parsons has done valuable and original work. In torpedo vessels of high speed the choice of the most efficient propellers has always been a matter of difficulty, and the solution of the problem has in many instances involved extensive experimental trials. By means of alterations in propellers alone, very large increases in speed have been effected; and even now there are difficulties to be faced. When Mr. Parsons adopted the extraordinary speed of revolution just named for the *Turbinia*, he went far beyond all experience and precedent and had to face unknown conditions. He has found the solution, after much patient and original investigation, in the use of multiple screws of small diameter. His results in this direction are of general interest to all who have to deal with screw propulsion.

Such radical changes in propelling machinery as are involved in the adoption of turbo-motors must necessarily be subjected to thorough test before they will be widely adopted. The experiment which the Admiralty are making is not on a small scale as regards power. Although it is made in a destroyer, about 10,000 horse-power will probably be developed and a correspondingly high speed attained. It may well happen that from this experiment very far-reaching effects may follow. Mr. Parsons himself has prepared many designs illustrating various applications of the system to sea-going, cross-Channel and special service vessels. Where shallowmess of draught is unavoidable, the small diameter of the screws possible with the quick-running turbines is clearly an important matter.

*Comparisons between Large and Small Vessels.*

It has been shown that the attainment of very high speeds by vessels of small size involves many conditions not applicable to large sea-going steamships. But it is equally true that in many ways the trials of small swift vessels constitute model experiments from which interesting information may be obtained as to what would be involved in driving ships of large size at speeds much exceeding any of which we have experience. When the progressive steam-trials of such small vessels can be studied side by side with experiments made on models to determine their resistance at various speeds, then the fullest information is obtained and the best guide to progress secured. This advantage, as has been said, we owe to William Froude.

His contributions to the Reports of the British Association are classics in the literature of the resistance and propulsion of ships. In 1874 he practically exhausted the subject of frictional resistance so far as it is known; and his Presidential Address to this Section in 1875 dealt fully and lucidly with the modern or stream-line theory of resistance. No doubt there would be advantage in extending Froude's experiments on frictional resistance to greater lengths and to ship-shaped forms. It is probable also that dynamometric determinations of the resistance experienced by ships of modern forms and considerable size when towed at various speeds would be of value if they could be conducted. These extensions of what Froude accomplished are not easily carried out; and in this country the pressure of work on shipbuilding for the Royal Navy has, for many years past, taxed to the utmost limits the capacity of the Admiralty experimental establishment so ably superintended by Mr. R. E. Froude, allowing little scope for purely scientific investigations, and making it difficult to deal with the numerous experiments incidental to the designs of actual ships. Now that Holland, Russia, Italy and the United States have equipped experimental establishments, while Germany and France are taking steps in that direction, we may hope for extensions of purely scientific work and additions to our knowledge. In this direction, however, I am bound to say that much might be done if experimental establishments capable of dealing with questions of a general nature relating to resistance and propulsion were added to the equipment of some of our universities and colleges. Engineering laboratories have been multiplied, but there is as yet no example of a model experimental tank devoted to instruction and research.

It is impossible, and possibly is unnecessary, to attempt in this Address any account of Froude's "scale of comparison" between ships and models at "corresponding speeds." But it may be of interest to give a few illustrations of the working of this method, in the form of a contrast between a destroyer of 300 tons, 212 feet long, capable of steaming 30 knots an hour, and a vessel of similar form enlarged to 765 feet in length and 14,100 tons. The ratio of dimensions is here about 3·61 : 1; the ratio of displacements is 47 : 1; and the ratio of corresponding speeds is 1·9 : 1.

To 12 knots in the small vessel would correspond 22·8 knots in the large vessel; and the resistance experienced by the large vessel at 22·8 knots (neglecting a correction for friction) should be forty-seven times that of the small vessel at 12 knots. By experiment, this resistance for the small vessel was found to be 1·8 tons. Hence, for the large vessel at 22·8 knots the resistance should be 84·6 tons. This would correspond to an "effective horse-power" of over 13,000, or to about 26,000 indicated horse-power. The frictional correction would reduce this to about 25,000 horse-power, or about 1·8 horse-power per ton. Now turning to the destroyer, it is found experimentally that at 22·8 knots she experiences a resistance of about 11 tons, corresponding to an effective horse-power of over 1700, and an indicated horse-power of about 3000: say 10 horse-power per ton, or nearly five and a half times the power per ton required in the larger vessel. This illustrates the economy of propulsion arising from increased dimensions.

Applying the same process to a speed of 30 knots in the large ship, the corresponding speed in the small ship is 15·8 knots. Her resistance at that speed is experimentally determined to be 3·5 tons, and the resistance of the large ship at 30 knots (neglecting frictional correction) is about 165 tons. The effective horse-power of the large ship at 30 knots is, therefore, about 34,000, corresponding to 68,000 horse-power indicated. Allowing for the frictional correction, this would drop to about 62,000 horse-power, or 4·4 horse-power per ton. For the destroyer at 30 knots the resistance is about $17\frac{1}{2}$ tons; the effective horse-power is 3600, and the indicated horse-power about 6000, or 20 horse-power per ton, nearly five times as great as the corresponding power for the large ship. But while the destroyer under her trial conditions actually reaches 30 knots, it is certain that in the large ship neither weight nor space could be found for machinery and boilers of the power required for 30 knots, and of the types usually adopted in large cruisers, in association with an adequate supply of fuel. The explanation of the methods by which the high speed is reached in the destroyer has already been given. Her propelling apparatus is about one-fourth as heavy in relation to its maximum power, and her load is only about one-third as great in relation to the displacement, when compared with the corresponding features in a swift modern cruiser.

It will, of course, be understood that in practice, under existing conditions, a cruiser of 14,000 tons would not be made 765 feet long, but probably about 500 feet. The hypothetical cruiser has been introduced simply for purposes of comparison with the destroyer.

The earlier theories of resistance assumed that the resistance experienced by ships varied as the square of the speed. We now know that the frictional resistances of clean-painted surfaces of considerable length vary as the 1·83 power of the speed. This seems a small difference, but it is sensible in its effects, causing a reduction of 32 per cent. at 10 knots, nearly 40 per cent. at 20 knots, and 42 per cent. at 25 knots. On the other hand, it is now known that the laws of variation of the residual or wave-making resistance may depart very widely from the law of the square of the speed, and it may be interesting to trace for the typical destroyer how the resistance actually varies.

Take first the *total resistance*. Up to 11 knots it varies nearly as the square of the speed; at 16 knots it has reached

the cube; from 18 to 20 knots it varies as the 3·3 power. Then the index begins to diminish: at 22 knots it is 2·7; at 25 knots it has fallen to the square, and from thence to 30 knots it varies, practically, as does the frictional resistance.

The residual resistance varies as the square of the speed up to 11 knots, as the cube at 12½ to 13 knots, as the fourth power about 14½ knots, and at a higher rate than the fifth power at 18 knots. Then the index begins to fall, reaching the square at 24 knots, and falling still lower at higher speeds.

It will be seen, therefore, that when this small vessel has been driven up to 24 or 25 knots by a large relative expenditure of power, further increments of speed are obtained with less proportionate additions to the power.

Passing from the destroyer to the cruiser of similar form but of 14,100 tons, and once more applying the "scale of comparison," it will be seen that to 25 knots in the destroyer corresponds a speed of 47½ knots in the large vessel. In other words, the cruiser would not reach the condition where further increments of speed are obtained with comparatively moderate additions of power until she exceeded 47 knots, which is an impossible speed for such a vessel under existing conditions. The highest speeds that could be reached by the cruiser with propelling apparatus of the lightest type yet fitted in large sea-going ships would correspond to speeds in the destroyer, for which the resistance is varying as the highest power of the speed. These are suggestive facts.

Frictional resistance, as is well known, is a most important matter in all classes of ships and at all speeds. Even in the typical destroyer this is so. At 12 knots the friction with clean-painted bottom represents 80 per cent. of the total resistance; at 16 knots 70 per cent; at 20 knots a little less than 50 per cent.; and at 30 knots 45 per cent. If the coefficient of friction were doubled and the maximum power developed with equal efficiency, a loss of speed of fully 4 knots would result.

In the cruiser of similar form the friction represents 90 per cent. at 12 knots, 85 per cent. at 16 knots, nearly 80 per cent. at 20 knots, and over 70 per cent. at 23 knots. If the coefficient of friction were doubled at 23 knots and the corresponding power developed with equal efficiency, the loss of speed would approximate to 4 knots.

These illustrations only confirm general experience that clean bottoms are essential to economical propulsion and the maintenance of speed, and that frequent docking is necessary in vessels with bare iron or steel skins, which foul in a comparatively short time.

### *Possibilities of further Increase in Speed.*

From the facts above mentioned it is obvious that the increase in speed which has been effected is the result of many improvements, and has been accompanied by large additions to size, engine-power and cost. These facts do not discourage the "inventor," who finds a favourite field of operation in schemes for attaining speeds of 50 to 60 knots at sea in vessels of moderate size. Sometimes the key to this remarkable advance is found in devices for reducing surface-friction by the use of wonderful lubricants to be applied to the wetted surfaces of ships, or by interposing a layer of air between the skins of ships and the surrounding water, or other departures from ordinary practice. If these gentlemen would "condescend to figures," their estimates, or guesses, would be less sanguine. In many cases the proposals made would fail to produce any sensible reduction in resistance; in others they would increase resistance.

Other proposals rest upon the idea that resistance may be largely reduced by adopting novel forms, departing widely from ordinary ship shapes. Very often small-scale experiments, made in an unscientific and inaccurate manner, are adduced as proofs of the advantages claimed. In other instances mere assertion is thought sufficient. Ordinarily no regard is had to other considerations, such as internal capacity, structural weight and strength, stability and seaworthiness. Most of these proposals do not merit serious consideration. Any which seem worth investigation can be dealt with simply and effectively by the method of model experiments. A striking example of this method will be found in the unusual form of a Parliamentary Paper (No. 313, of 1873), containing a report made by Mr. William Froude to the Admiralty. Those interested in the subject will find therein much matter of special interest in connection with the conditions attending abnormally high speeds. It must suffice now to say that ship shaped forms are not likely to be superseded at present.

The most prolific "inventions" are those connected with supposed improvements in propellers. One constantly meets with schemes guaranteed by the proposers to give largely increased efficiency and corresponding additions to speed. Variations in the numbers and forms of screws or paddles, the use of jets of water or air expelled by special apparatus through suitable openings, the employment of explosives, imitations of the fins of fishes and numberless other departures from established practice are constantly being proposed. As a rule the "inventors" have no intimate knowledge of the subject they treat, which is confessedly one of great difficulty. When experiments are adduced in support of proposals they are almost always found to be inconclusive and inaccurate. More or less mathematical demonstrations find favour with other inventors, but they are not more satisfactory than the experiments. An air of great precision commonly pervades the statements made as to possible increase in efficiency or speed. I have known cases where probable speeds with novel propellers have been estimated (or guessed) to the third place of decimals. In one such instance a trial was made with the new propeller, with the result that instead of a gain in efficiency there was a serious loss of speed. Very few of the proposals made have merit enough to be subjected to trial. None of them can possibly give the benefits claimed.

It need hardly be added that in speaking thus of so-called "inventors" there is no suggestion that improvement has reached its limit, or that further discovery is not to be made. On the contrary, in regard to the forms of ships and propellers, continuous investigation is proceeding and successive advances are being made. From the nature of the case, however, the difficulties to be surmounted increase as speeds rise; and a thorough mastery of the past history and present condition of the problems of steamship design and propulsion is required as a preparation for fruitful work in the nature of further advance.

It would be idle to attempt any prediction as to the characteristic features of ocean navigation sixty years hence. Radical changes may well be made within that period. Confining attention to the immediate future, it seems probable that the lines of advance which I have endeavoured to indicate will remain in use. Further reductions may be anticipated in the weight of propelling apparatus and fuel in proportion to the power developed; further savings in the weight of the hulls, arising from the use of stronger materials and improved structural arrangements; improvements in form; and enlargement in dimensions. If greater draughts of water can be made possible, so much the better for carrying power and speed. For merchant vessels commercial considerations must govern the final decision; for warships the needs of naval warfare will prevail. It is certain that scientific methods of procedure and the use of model experiments on ships and propellers will become of increased importance.

Already avenues for further progress are being opened. For example, the use of water-tube boilers in recent cruisers and battleships of the Royal Navy has resulted in saving *one-third* of the weight necessary with cylindrical boilers of the ordinary type to obtain the same power, with natural draught in the stokeholds. Differences of opinion prevail, no doubt, as to the policy of adopting particular types of water-tube boilers; but the weight of opinion is distinctly in favour of some type of water-tube boiler in association with the high steam pressures now in use. Greater safety, quicker steam-raising and other advantages, as well as economy of weight, can thus be secured. Some types of water-tube boilers would give greater saving in weight than the particular type used in the foregoing comparison with cylindrical boilers.

Differences of opinion prevail also as to the upper limit of steam pressure which can with advantage be used, taking into account all the conditions in both engines and boilers. From the nature of the case, increases in pressure beyond the 160 to 180 lbs. per square inch commonly reached with cylindrical boilers cannot have anything like the same effect upon economy of fuel as the corresponding increases have had, starting from a lower pressure. Some authorities do not favour any excess above 250 lbs. per square inch on the boilers; others would go as high as 300 lbs., and some still higher.

Passing to the engine-rooms, the use of higher steam-pressures and greater rates of revolution may, and probably will, produce reductions in weight compared with power. The use of stronger materials, improved designs, better balance of the moving parts, and close attention to details have tended in the

same direction without sacrifice of strength. Necessarily there must be a sufficient margin to secure both strength and endurance in the motive power of steamships. Existing arrangements are the outgrowth of large experience, and new departures must be carefully scrutinised.

The use of rotary engines, of which Mr. Parsons' turbo-motor is the leading example at present, gives the prospect of further economies of weight. Mr. Parsons is disposed to think that he could about halve the weights now required for the engines, shafting, and propellers of an Atlantic liner while securing proper strength and durability If this could be done in association with the use of water-tube boilers it would effect a revolution in the design of this class of vessel, permitting higher speeds to be reached without exceeding the dimensions of existing ships.

It does not appear probable that, with coal as the fuel, water-tube boilers will surpass in economy the cylindrical hoilers now in use; and skilled stoking seems essential if water-tube boilers are to be equal to the other type in rate of coal consumption. The general principle holds good that as more perfect mechanical appliances are introduced, so more skilled and disciplined management is required in order that the full benefits may be obtained. In all steamship performance the "human factor" is of great importance, but its importance increases as the appliances become more complex. In engine-rooms the fact has been recognised and the want met. There is no reason why it should not be similarly dealt with in the boiler-rooms.

Liquid fuel is already substituted for coal in many steamships. When sufficient quantities can be obtained it has many obvious advantages over coal, reducing greatly manual labour in embarking supplies, conveying it to the boilers and using it as fuel. Possibly its advocates have claimed for it greater economical advantages over coal than can be supported by the results of extended experiment. Even if the saving in weight for equal evaporation is put as low as 30 per cent. of the corresponding weight of coal, it would amount to 1000 tons on a first-class Atlantic liner. This saving might be utilised in greater power and higher speed, or in increased load. There would be a substantial saving on the stokehold staff. At present it does not appear that adequate supplies of liquid fuel are available. Competent authorities here and abroad are giving attention to this question, and to the development of supplies. If the want can be met at prices justifying the use of liquid fuel, there will undoubtedly be a movement in that direction.

Stronger materials for the construction of hulls are already available. They are, however, as yet but little used, except for special classes of vessels. Mild steel has taken the place of iron, and effected considerable savings of weight. Alloys of steel with nickel and other metals are now made which give strength and rigidity much superior to mild steel, in association with ample ductility. For destroyers and torpedo boats this stronger material is now largely used. It has also been adopted for certain important parts of the structures of recent ships in the Royal Navy. Of course the stronger material is more costly, but its use enables sensible economies of weight to be made. It has been estimated, for example, that in an Atlantic liner of 20 knots average speed about 1000 tons could be saved by using nickel steel instead of mild steel. This saving would suffice to raise the average speed more than a knot, without varying the dimensions of the ship.

Alloys of aluminium have also been used for the hulls or portions of the hulls of yachts, torpedo-boats, and small vessels. Considerable savings in weight have thus been effected. On the other hand, these alloys have been seriously corroded when exposed to the action of sea-water, and on that account are not likely to be extensively used. Other alloys will probably be found which will be free from this defect, and yet unite lightness with strength to a remarkable degree.

Other examples might be given of the fact that the metallurgist has by no means exhausted his resources, and that the shipbuilder may look to him for continued help in the struggle to reduce the weights of floating structures.

It is unnecessary to amplify what has already been said as to possible increase in the efficiency and types of propellers. With limited draught, as speeds increase and greater powers have to be utilised, multiple propellers will probably come into use. Mr. Parsons has shown how such problems may be dealt with; and other investigators have done valuable work in the same direction.

In view of what has happened and is still happening, it is practically certain that the dimensions of steamships have not yet attained a maximum.

Thanks to mechanical appliances, the largest ships built or to be built can be readily steered and worked. In this particular difficulties have diminished in recent years, notwithstanding the great growth in dimensions.

Increase in length and weight favour the better maintenance of speed at sea. The tendency, therefore, will be to even greater regularity of service than at present. Quicker passages will to some extent diminish risks, and the chance of breakdown will be lessened if multiple propellers are used. Even now, with twin screws, the risk of total breakdown is extremely small.

Whatever may be the size and power of steamships, there must come times at sea when they must slow down and wait for better weather. But the larger and longer the vessel, the fewer will be the occasions when this precaution need be exercised.

It must never be forgotten that as ships grow in size, speed, and cost, so the responsibilities of those in charge increase. The captain of a modern steamship needs remarkable qualities to perform his multifarious duties efficiently. The chief engineer must have great powers of organisation, as well as good technical knowledge, to control and utilise most advantageously the men and machinery in his charge. Apart from the ceaseless care, watchfulness and skill of officers and men, the finest ships and most perfect machinery are of little avail. The "human factor" is often forgotten, but is all-important. Let us hope that in the future, as in the past, as responsibilities increase so will the men be found to bear them.

## *NOTES.*

A STATUE, erected in memory of the late M. F. Tisserand, will be unveiled at Nuits-Saint-Georges on October 15.

MAJOR RONALD ROSS has sent Mr. A. L. Jones a letter from Sierra Leone on his investigations into the cause of malaria. In the course of the communication he says:—We have now practically finished our work here. We have found—(*a*) that local species of Anopheles (mosquitoes) carry malaria; (*b*) that these species breed in a few stagnant puddles. For many scientific reasons we have come to the conclusion that the truly malarial fever is caused here solely by the mosquito—probably entirely by the Anopheles species. We estimate then that most of the malarial fever here can be got rid of at almost no cost except of a little energy on the part of the local authorities.

A SUCCESSION of earthquake shocks occurred on Monday night, September 25, in the district of Darjeeling, involving great loss of life and damage to property. No details as to the exact times of the shocks have been received. The earthquake was accompanied by a remarkable rainfall, and was followed by extensive landslips. It is reported that in twenty-four hours over 20 inches of rain fell, and in all 28 inches fell in thirty-eight hours.

THE associate editorship of the *American Journal of Science*, vacant by the death of Prof. Marsh, has been taken up by Prof. L. V. Pirsson, of Yale College.

IN a report just issued on metalliferous mines in the North Wales district, Dr. C. Le Neve Foster refers to the fact that several foreign companies have lately purchased mines in that district with the object of reworking them. He remarks:—"Though I welcome the advent into Wales of the famous Vieille Montagne Company, for I have hopes that its methods of mining and dressing will form useful object-lessons to us, I am not blind to the slur which is cast upon us as a mining nation. If such a capable body of commercial men as the directors of the Vieille Montagne Company propose to resuscitate some of our abandoned mines, it may be taken for granted that they consider the enterprise as likely to be profitable. Is our mining talent so far behind the times that foreigners can make a profit out of mines which we have abandoned as worthless? If so, the

technical skill of continental mining engineers is of a higher nature than that of our own people, and we are not keeping pace with the times. It therefore behoves us as a nation to get out of the groove of the slovenly old-fashioned methods of working ore mines, which linger so long in this country, and to give our mining superintendents and mining foremen such technical training as will render them at least the equals of their continental competitors." It is to be hoped that this note of warning will lead British mining companies to make use of the resources which modern science has placed at their disposal.

THE *Journal* of the Society of Arts announces that among the prizes offered by the French Société d'Encouragement pour l'Industrie Nationale, open to all the world except members of the administrative council, and to be awarded next year, are the following :—Two thousand francs (80*l.*) for a publication useful to the chemical or metallurgical industry, a treatise on metallurgical chemistry summarising the works that have appeared on the subject during the last twenty years being invited ; two prizes of 500 francs (20*l.*) each for scientific chemical researches the results of which are useful to industry, the authors not being required to have realised the practical applications which they may foresee as resulting from their observations ; 2000 francs (80*l.*) for the scientific study of an industrial process the theory of which is still imperfectly known, the methods that permit of obtaining a given result being often known long before the nature of the phenomena is suspected, and yet the knowledge of which has great interest as regards reducing the number of empirical trials necessary for realising fresh improvements ; and 3000 francs (120*l.*) for the production of permanent magnets, the qualities expected from which are power and stability. The models, papers, descriptions, &c., must be sent in before December 31 to the Secretary of the Société d'Encouragement, 44 Rue de Rennes, Paris.

THE death is announced of Mr. Edward Case, the author of a paper on "The Dymchurch Wall and Reclamation of Romney Marsh," read at the recent meeting of the British Association. For many years Mr. Case was a superintending engineer in the Public Works Department in Ceylon. Of late he gained distinction in the engineering world by his investigations of the problem of sea defence, and by the results which he had obtained on a variety of shores.

THE Funafuti Boring Expedition has very recently led to the rectification of a common ethnographical error, and the discovery of an interesting fact in zoo-geography. In the Monograph on the Atoll of Funafuti published by the Australian Museum, Sydney (part iii. 1897, p. 199) Mr. E. R. Waite referred to a large undetermined fish known to the natives as "Palu," and to traders as "Oil-fish." According to Mr. Louis Becke, a full-grown Palu would weigh up to 150 lbs. and be 6 feet long ; the average size is about 3 or 4 feet, and weight 40 to 60 lbs. The natives have many superstitions in regard to Palu ; every portion of it is edible, even the head and bones when cooked turning into a rich mass of jelly. The flesh of the Palu, if left uncooked, never putrefies ; it simply dissolves into a colourless and odourless oil. Perhaps the great regard the natives have for it is due to the fact of its being a rapid and powerful purgative. It is a deep-water fish, and is usually caught at a depth of from 120 fathoms down to 200 fathoms ; the fishing is only done at night. The Palu fishing-hook has been described by Mr. C. Hedley (*l.c.* part iv., 1897, p. 272), who points out that this large hook, which is widely distributed in the Central Pacific, and may be seen in most ethnographical collections, has been described by all authors as a "shark-hook." The last expedition to Funafuti has been fortunate enough to obtain a specimen of this fish, and in an appendix (part ix., 1899, p. 539) Mr. Waite has solved the riddle, and found that this mysterious fish is the well-known *Ruvettus pretiosus*, which hitherto was known only from the North Atlantic, and whose recorded range is now enormously increased. The Escolar (Atlantic name) has been taken at depths as great as 300 and 400 fathoms, but can be taken only at night in September and the early part of October.

WE learn from the September number of *Annalen der Hydrographie* that the Deutsche Seewarte, in conjunction with the Berlin Meteorological Office, proposes to issue a ten-day report, containing values of barometric pressure, air-temperature and rainfall for, say, one hundred stations between the west coast of North America and the east coast of Asia, accompanied by a map showing observations taken on board German ships traversing the North Atlantic. The report would be issued as a supplement to the *Daily Weather Bulletin*, about twenty days after date. The success of the proposal will to a great extent depend upon the willingness of other countries to furnish ten-day means for some selected stations in their respective systems.

WE have received from Dr. W. Doberck, Government Astronomer, Hong Kong Observatory, his annual report for 1898. The "Observations and Researches" contain synopses of fifteen years' meteorological and magnetic observations and a number of very useful tables relating to the climatology of the Colony.

THE papers read at the ninth annual general meeting of the Museums Association, held in Sheffield in July of last year, are contained in the "Report of Proceedings," just published by Messrs. Dulau and Co. All the subjects dealt with are of interest to every one concerned in museum work, among them being : the relation of museums to elementary education ; the arrangement of museum herbaria, the electric light installation at the Manchester Museum, the exhibition of museum specimens, the mounting of marine animals as transparencies for museum purposes, the ethnological arrangement of archæological material, and some Russian museums. Mr. Herbert Bolton, the editor of the volume, calls attention to the need for a complete report or directory of museums in the United Kingdom, and rightly remarks that "the publication of such a report, and its annual revision, would tend to bring museums into close union and to a common knowledge of each other." It is pointed out that the preparation of an annual report of this character might be undertaken by a committee of the British Association ; and this suggests that it would be worth considering whether the Museums Association itself might not with advantage become part of the British Association, in much the same way as the Corresponding Societies are at present. The multiplication of annual meetings would thus be avoided, and excellent opportunity would be afforded for the discussion of the various aspects of museum work.

IN No. 4 of vol. i. of the "Geological Series" of the Field Columbian Museum Mr. Elmer S. Riggs treats of the Mylagaulidæ, an extinct family of rodents of which two new genera are described. It is remarked that the one prominent feature in these animals is the unusual development of the premolar to the exclusion of the posterior-lying teeth, evincing unusual capacity for crushing or grinding. A fossil egg from South Dakota is described in No. 5, by Dr. Oliver C. Farrington. The specimen is about 2 inches long by $1\frac{1}{2}$ inches. Covering most of the exterior is a thin black layer ·017 of an inch in thickness, and resembling an eggshell. The mass of the specimen is chalcedony, and this contains a white opalescent ovoid mass which appears to correspond with the yolk, and to yield evidence of organic matter. In shape this petrified egg resembles that of the Florida duck.

THE jumping-mice of the genus *Zapus* form the subject of part 15 of the "North American Fauna," edited by Dr. Merriam. It is noteworthy that whereas Dr. Coues in 1877 recognised but a single representative of this genus, ranging over a large area in North America, Mr. Preble, the author of the present memoir, considers himself justified in distinguishing no less than twenty North American species and sub-species, in addition to one Old World form recently described from Szechuan. The discovery of the Szechuan species adds one more link in the chain connecting the fauna of North-eastern Asia and North America; and when Manchuria and Mongolia are fully explored, representatives of the genus may be looked for in those countries.

ANOTHER important contribution to our knowledge of the North American mammal fauna is afforded by Dr. Allen's revision of the squirrels inhabiting the area north of Mexico, published in the August number of the *American Naturalist*. The last revision was in 1877, when six species and seven sub-species were recognised; Dr. Allen now admits ten species, with a large number of sub-species. With Mr. Nelson's revision of the species inhabiting Mexico and Central America, the group is now placed on a satisfactory footing, except as regards South America. Interesting results have been obtained by both writers as regards the effects of temperature and humidity on the coloration of members of the group. "In the drier interior mountains," for example, "certain sub-species of a group will be characterised by dull greyish upper-parts and white under-parts, while other sub-species of the same group inhabiting humid mountains near the coast will have nape and rump-patches sharply contrasting with the rest of the dorsal surface and bright ferruginous under-parts; increased humidity within the tropics being usually accompanied by increased intensity of coloration." This is zoology in its best sense.

A NOTEWORTHY addition to the fauna of the Australasian region is afforded by the discovery of a representative of the genus Balanoglossus in the New Zealand seas, since it has hitherto been unknown in the southern hemisphere, as, indeed, was the entire group of the Hemichordata till Mr. T. P. Hill found a species of Ptychodera in 1893. The new Balanoglossus is described by Mr. Benham in the September number of the *Quart. Journ. Microscopical Science*, and presents all the characteristic features of the genus. We may remind our non-zoological readers that Balanoglossus includes worm-like animals which approximate to vertebrates in the possession of a notochordal tract.—The same journal contains an interesting paper by Mr. E. S. Goodrich, of Oxford, on the existence of a communication between the blood-vascular system and the "cœlom" in the common leech.

YET another communication in the journal above quoted cannot be passed over without notice, although, from the extremely technical nature of the subject, such mention must necessarily be brief. The paper in question, which has been awarded the Rolleston Memorial Prize for 1898, is one by Mr. R. Evans, on the structure and metamorphosis of the larva of the common freshwater sponge. The work, which occupied a large portion of the author's time for a period of about eighteen months, was undertaken on the suggestion of Prof. Ray Lankester, and appears to have been admirably carried out. Several types of free-swimming larvæ have been detected, and their mutual relationship determined. From the occurrence of so-called "collar-cells" in sponges, and their early appearance in the free-swimming larvæ, coupled with their absence in all the Metazoa, the author is inclined to believe that the Porifera (sponges) have no relationship with the former group, but are more probably derived independently from primitive flagellate organisms.

IN their report for the year 1898 the Trustees of the Australian Museum, Sydney, deplore the insufficiency of the Government grant for purchase of specimens. It appears that in 1892, when the purchase grant was 1250*l*., the Colony was passing through a period of financial depression, in consequence of which the vote was reduced in the following year to 200*l*., this small amount having to suffice for the purchase of books as well as specimens. Although this amount has been slightly increased in the vote for 1898–99, the Trustees point out that it is altogether insufficient for the needs of the institution, so that many specimens are lost to the museum, while collecting has had to be suspended altogether. As the opportunity to acquire many of the ethnological specimens offered will never recur, it is to be hoped that Government, now that the finances of the Colony have taken such a decided turn for the better, may see their way to place the Trustees in a stronger position for carrying out the purposes for which the museum was founded.

MUCH more satisfactory reading than the foregoing is Dr. E. Thurston's report on the Madras Museum for 1898–99. As was fully stated in NATURE for May 26, 1898, the Director has been chiefly occupied in the investigation of the ethnology of the numerous native tribes of the Nilgiri and Anamalai Hills; the results of which are in course of publication in a series of valuable memoirs. Attention is directed in the report to the prospect of acquiring Mr. R. B. Foote's well-known collection of prehistoric Indian implements. It is also satisfactory to learn that the importance of fishery investigations is fully recognised by the Director.

MESSRS. HOLBORN AND DAY send us a reprint from *Wiedemann's Annalen* dealing with their investigations on the air-thermometer at high temperatures, a subject to which attention has been drawn by the recent discussions on platinum-thermometry at the British Association. The authors give comparisons of the results obtained by using containing vessels of platinum, iridium and porcelain respectively in these observations.

FROM Messrs. O. Lummer and E. Pringsheim we have received a copy of their paper on the partition of energy in the spectrum of a black body, published in the *Verhandlungen* of the German Physical Society (1). Experiments are described in which the radiations from an electrically heated cylinder were allowed to fall on a bolometer, and the energy tabulated for different temperatures and wave-lengths, the results being compared with those given by Paschen's formula.

IN the course of a paper on Euclidian geometry, contributed to the *Bulletin de la Classe des Sciences* (Brussels), M. Charles Lagrange remarks that the condition necessary for introducing doubts in geometry, a condition without which no argument exists against the certainty of Euclidian space, would consist in presenting two different admissible definitions of space. Up till now only one definition has been given; and this assumes the existence of Euclidian space. The author considers that the new geometry has in fact established the contrary of what it claimed; it has attempted to throw doubts on the physical reality of the Euclidian postulate, and it has only succeeded in confirming it.

ENGLER AND PRANTL's great work, *Die natürlichen Pflanzenfamilien* is now completed, as far as flowering plants are concerned, by the publication of Nos. 184 5, completing Parts ii.–v.

PROF. D. G. FAIRCHILD, of the U.S. Department of Agriculture, gives, in the *Botanical Gazette* for August, an interesting sketch of the general features of the flora of Venezuela, derived from his experience as botanist to the expedition fitted out by

Mr. Barbour Lathrop, of Chicago, for the exploration of that country.

IN honour of the 150th anniversary of the birth of Goethe (August 28, 1899), Dr. H. Potonié reprints, from his *Naturwissenschaftliche Wochenschrift*, a treatise on the morphological origin of the leaves of plants. The importance is shown of the part played by Goethe's theory of metamorphosis in the elucidation of problems connected with vegetable morphology, and it is pointed out that the introduction of the term "morphology" itself is due to Goethe.

VOLUME XV., part 7 of the *Nouveaux mémoires de la Soc. Imp. des Naturalistes de Moscou* is chiefly occupied by a monograph of the genus Sphæronema (Ascomycetes) by M. A. Jaczewski. He enumerates and describes seventy-two good specimens of the genus, seventy-seven being rejected as not properly belonging to it, besides eight others, for which a new genus, Pseudographium, is formed. D. Strémonkhoff has also a short paper on the ammonites *Phylloceras zignodianum* and *Lytoceras adelae*, from the schists of Balaclava.

PROF. VERNON L. KELLOGG gives an interesting account, in the *American Naturalist* for August, of the Hopkins Sea-side Laboratory on the Bay of Monterey, connected with the Leland Stanford Junior University. Monterey Bay and the Bay of Naples are stated to be much alike in the abundance and representation of species. The Bay is a middle point between the north and south zones of the Pacific coast. The regular sessions of the laboratory are held in June and July of each year; but investigators and students working without instruction may continue their work though the summer. Courses of lectures are given in general zoology, embryology and cryptogamic botany.

PRACTICAL directions for stuffing and setting up birds are given in "Bird Stuffing and Mounting," the fifth edition of which has been published by Messrs. J. and W. Davis, Dartford. To students of natural history and collectors this practical manual of taxidermy should be of service.

IN connection with the Parents' National Education Union, a course of lectures to young people will be delivered by Mr. Cecil Carus-Wilson at the Horbury Rooms, Notting Hill Gate, during this month and next. The titles of the lectures are "The Wonders of Rain," "Ice and Glaciers," "The Mighty Ocean," "Volcanoes and Geysers." The aim will be to interest and entertain children by directing their attention to the natural phenomena which surround them, and upon which the studies of geography, geology and physiography are based.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*, ♂) from India, presented by Dr. Montgomery Smith; an African Civet Cat (*Viverra civetta*) from West Africa, presented by Mr. W. H. Hardwick, R.N.; a Two-spotted Paradoxure (*Nandinia binotata*) from West Africa, presented by Mr. F. Gordon; a Black-backed Kaleege (*Euplocamus melanonotus*, ♀), two Sonnerat's Jungle Fowls (*Gallus sonnerati*, ♀ ♀), a Wood Francolin (*Francolinus gularis*) from India, presented by Mr. W. F. Pedler; four Green Lizards (*Lacerta viridis*), European, presented by Mr. F. K. Preston; two Black-eared Marmosets (*Hapale penicillata*) from South-east Brazil, a Hocheur Monkey (*Cercopithecus nictitans*), a Ruppell's Parrot (*Paeocephalus rueppelli*) from West Africa, a Maroon Oriole (*Oriolus trailii*) from India, two Radiated Tortoises (*Testudo radiata*) from Madagascar, deposited.

## OUR ASTRONOMICAL COLUMN.

NEW ALGOL VARIABLE IN CYGNUS.—The following *minima* occur at convenient times for observation during October:—

$$\text{D.M.} + 45^\circ\cdot 3062. \begin{cases}\text{R.A. 20h. } 2\cdot 4\text{m.}\\ \text{Decl.} + 45^\circ\ 53'\end{cases} (1855)$$

|---|---|---|---|---|---|---|---|---|---|
| 1899. | Oct. | 5 | 8 | 43 | 1899. | Oct. | 23 | 15 | 43 |
| ,, | ,, | 14 | 12 | 13 | ,, | ,, | 28 | 5 | 28 |

STELLAR PARALLAX.—M. Osten Bergstrand, of the Upsala Observatory, has recently been engaged in measuring photographic chart plates to determine any possible evidence of stellar parallax (*Astr. Nach.*, Bd. 150, No. 3593). The photographs were taken with the photographic refractor of 33 cm. aperture and 4·33 metres focal length during 1897 and 1898, all the measures being made with a Repsold micrometer in conjunction with a "reseau" by Gautier. After describing the method of measurement adopted, the following values for parallax are given:—

| Star. | Parallax. | |
|---|---|---|
| Σ 1516 A. | $+0''\cdot 080 \pm 0''\cdot 011$. | From measures of *four* comparison stars on *fourteen* plates. |
| A Oe. 11677 | $+0''\cdot 192 \pm 0''\cdot 013$. | From measures of *eight* comparison stars on *nine* plates. |

The latter star is remarkable as having a very large proper motion—about 3″ annually.

PRECESSION TABLES.—We have received a volume compiled by Dr. Downing, superintendent of the English Nautical Almanac, containing a series of tables which have been constructed so as to give the values of the precessions corresponding to Newcomb's value of the Precessional Constant, as deduced by him in accordance with the request made to him at the International Conference on Fundamental Stars, held in Paris in May 1896. Prof. Newcomb's original results are published in the Astronomical Papers of the American Ephemeris, vol. viii. part i. The present tables are constructed for Epoch 1910·0, but the method of setting out is such that they can be used with facility for at least ten years before and after that date.

LONGITUDE FROM MOON CULMINATIONS.—In a communication to the Royal Astronomical Society (*Monthly Notices*, R.A.S., vol. lix. p. 513, May 1899), Mr. D. A. Pio, of Syra, Greece, brings forward a new method of determining local longitude. The determination of culmination is only undertaken to give the precise instant of the moon's transit across the local meridian, thereby obviating the necessity of an accurately adjusted transit instrument with the many precautions connected with it. The instruments required are a sextant, artificial horizon, and a well-rated chronometer, together with the usual tables. Instead of finding the right ascension of the moon directly as usual, the author obtains it indirectly by finding the mean local time of meridian passage, converting to sidereal time, and then adding the right ascension of the mean sun at local transit. The difficulty of finding the mean local time of transit is got over by observations of equal altitudes, the resulting *time of culmination* requiring to be corrected to reduce it to *time of transit*. Local mean time is determined by similar measures of equal altitudes of the sun. The difference between the times of transit of sun and moon thus obtained is, of course, the mean local time of the moon's transit. The remaining calculations are precisely similar to the usual method of lunar distances, so that the novelty of the new method consists in the substitution of the use of "equal altitudes" with a sextant for meridian passage with a transit circle; in fact the observation is really a chronometric one. The difference in time between the transits of sun and moon should be correct to the *tenth* of a second, and to facilitate this the two observations should be chosen as near together as possible. The method is stated to be unsuitable for high latitudes. The necessary formulæ for "reduction to meridian" are included in the article, and an example fully worked out to illustrate the exact method of procedure.

## THE ROYAL PHOTOGRAPHIC SOCIETY'S EXHIBITION.

THE forty-fourth annual exhibition of the Royal Photographic Society was opened to the public last Monday at the Gallery of the Royal Society of Painters in Water Colours, 5A Pall Mall East. As is usual, by far the greater number of the exhibits claim attention on account of their pictorial interest; but the technical and scientific section is considerably larger than it has been at the recent exhibitions. No doubt next year there will be a still further increase in the importance of this section, as the Society will then have at their disposal the larger accommodation available at the New Gallery in Regent Street.

The judges in this Section, Captain Abney, Mr. T. Bolas and Mr. Chapman Jones, have selected three of the exhibits as showing progress of sufficient importance to merit the special distinction of receiving the Society's medal Taking these as they stand in the catalogue, the first is awarded for copies of an etching, a mezzotint, a silver print, an engraving, a lithograph, a pen and ink drawing and a pencil drawing, by Mr. J. Hort Player, by what he calls the "absorption" process. The method is to place the picture or document that is to be copied face uppermost, to lay upon it a piece of "bromide paper" with its sensitive surface in close contact with the picture, and then to expose with the bromide paper towards the light, so that the light passes through the sensitive surface before it comes in contact with the picture being copied. On development this furnishes a negative from which prints are obtained as usual. The great advantage of the process is that the picture or document need not be transparent, or if it is on ordinary paper there may be other writing or drawing on the reverse side. Those who examine these specimens of Mr. Player's will be surprised at the wonderful perfection to which he has brought the process, and its universal applicability is proved by the great variety in the character of the originals that he has worked from.

Another medal is awarded for a cross-lined screen for use in the making of half-tone photo-typographic blocks, by Messrs. J. E. Johnson and Co. It has two hundred lines to the inch over its whole area of thirteen by sixteen inches, the especial feature of the screen being the great regularity of the ruling and the freedom from blemishes in so large a plate. Two still larger ruled screens are also shown by the same firm, of 133 and 150 lines to the inch respectively.

Mr. E. Sanger Shepherd receives a medal for his "trichromatic light filters." The three-colour printing methods that have been brought to such perfection depend upon the fact that the phenomena of colour vision can be explained on the assumption of three colour sensations. By photographing separately the light that affects each of these, and superposing the prints from the negatives, each being printed in its corresponding colour, the same sensation of colour will be produced by the resulting composite print as by the original. In order to photograph separately the colours that correspond to each sensation it is necessary to stop the light that is not wanted by means of a suitably coloured screen, which is generally placed against the lens. But these colour screens have also to compensate for the differences between the sensitiveness of the plate used for the different colours and their visual intensity. Heretofore we believe the colour screens have been prepared by the method of trial and error, and though astonishingly good results have sometimes been produced, we may well expect greater certainty and more definite success by the use of screens that have been adjusted by definite methods of measurement as these of Mr. Sanger Shepherd's have been. The screens are adjusted to the Cadett "rapid spectrum plate" and tested by the colour sensitometer recently devised by Captain Abney. The exact tints are obtained by the superposition in each case of films variously dyed.

Among the cameras shown, the "Gambier-Bolton" hand camera by Messrs. Watson and Sons is worthy of especial attention, as embodying the requirements found by Mr. Bolton in his large experience in photographing animals. The camera is for 5 × 4 inch plates, and is by no means a compact apparatus suitable for carrying about for obtaining snap-shots. It is designed for lenses of much greater focal length than usual that the image may be large, and as the lenses must be rapid, they must be large and consequently heavy. The camera has many conveniences adapting it to the special work it is constructed for. The same exhibitors show the "Kromaz" colour apparatus. This is somewhat analogous to Ives' well-known "Kromscop," its only merit presumably being that it is cheaper. Instead of taking a complete stereoscopic negative for each of the three colours, only two pairs of negatives are taken—one through a green screen, and one of the other pair through a red and the other through a blue screen. The view shown is crude, and hardly comparable with the exquisite results obtained with Ives' "Kromscop."

The Lippmann interference colour process is exemplified by three photographs by Mr. Edgar Senior—two views and a spectrum of the arc light. These would show to better advantage if the correct position of the eye were indicated in each case. The views are very good specimens of the results obtainable by this method, but the spectrum is especially worthy of commendation. In addition to these there will be found upon the tables many little conveniences, some of a distinctly novel kind, that will prove of service to those who photograph either for scientific purposes or for mere pleasure. A small printing frame, with six slides so that the sensitive surface may be exposed in six separate strips, is exhibited by Messrs. Marion and Co., and is applicable to a great variety of experimental purposes; and a frame, by Mr. T. Webster, that opens like a book, the negative being entirely removed from the print, so that the whole of the print may be examined at any time, though perhaps not very novel in principle, is likely to prove useful.

But the most remarkable of all the exhibits is not mentioned in the catalogue, although examples will be found on the tables. These are some plates prepared by General Waterhouse, the honorary secretary of the Society, to illustrate the fact that a polished surface of metallic silver is sensitive to light, and that the resulting latent image may be developed by mercury vapour, after the manner of daguerreotype plates, or by the methods of so-called physical development, after the manner of wet collodion plates. The exposures necessary are long, generally two to three hours, to direct sunshine in August. To exclude any effect of the stencil plate used as the negative to print from, a sheet of mica was placed between it and the silver surface, and the silver surfaces experimented with have been electroplated copper plates prepared for daguerreotype work, silver foil and commercial silvered glass, the surface in each case being polished with plate powder. The surfaces of other metals have given similar results. Many years ago Moser made similar experiments, developing the images with the vapour of water and of mercury, but (speaking without reference) we think that he did not go so far as to develop the images by the deposition upon them of silver from a solution. General Waterhouse seems to have brought these experiments and practical photography a little nearer together, and we shall receive with great interest any further results of his investigations. C. J.

## UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

DR. A. WILLEY, formerly Balfour Student of the University of Cambridge, has been appointed Lecturer on Biology in Guy's Hospital.

THE inaugural address of the coming session of the City and Guilds Central Technical College will be given at the College, in Exhibition Road, on Tuesday afternoon next, at three o'clock, by Sir Andrew Noble.

*Science* makes the following announcement:—The plans for building the University of California, submitted by M. Bernard, of Paris, have received the first prize in the competition arranged by Mrs. Phœbe Hearst. The cost of the buildings is estimated at over 15,000,000 dollars.

IN addition to 300,000 dollars subscribed from various sources for an endowment of Brown University, made on condition that 2,000,000 dollars be collected, Mr. John D. Rockefeller has offered to give 250,000 dollars on condition that 1,000,000 dollars be obtained before the commencement of next year.

A PROSPECTUS just received shows that the work of the South African School of Mines, Kimberley, is now carried on in suitable premises, which were completed in the beginning of this year at a cost of about 9000*l*. Of this sum, 2000*l*. was given by the Government of Cape Colony, 2000*l*. by the De Beers Company, and 5000*l*. was borrowed. The school has been established to carry out part of a scheme for the training of

mining engineers in South Africa. The courses of instruction are intended to prepare students for a diploma of mining engineer, or for the degrees of B.Sc. or M.Sc. in mining engineering. Theoretical and practical instruction is given, under the direction of the principal, Mr. James G. Lawn, in mining, mechanical and electrical engineering, metallurgy, assaying, surveying and other subjects. Practical work is carried on in the mines and workshops of the De Beers Company, and also in various mines at Johannesburg. The time spent at Johannesburg is devoted to a special study of the cyanide process in all its developments, of the electrical machines and appliances at the mine where the student is working, of the methods of assaying and surveying and of the economics of mining on the Rand. A thorough training for mining engineers is thus provided in connection with the school, the course of work described in the prospectus being of a very satisfactory character.

THE London Technical Education Board have arranged several advanced evening science courses in connection with King's and University Colleges, to commence next month. The courses of instruction will afford an opportunity to students who can study only in the evenings to obtain instruction in well-equipped University laboratories, and will make available to evening students the same advantages as are enjoyed by University day students, but they are only intended for those who are practically engaged during the day in some trade, business or occupation.—A course of twenty lectures on civil engineering will be given by Prof. Robinson, at King's College, on Mondays, from 7 to 9, commencing on Monday, October 9. Part of the time will be spent in working out engineering calculations by graphical methods.—A course of about twenty demonstrations will be given by Prof. Capper and Mr. H. M. Waynford, at King's College, on Thursday evenings, 7 to 9, upon "Steam and Gas Engines and General Laboratory Work," commencing October 12. The latter portion of each evening will be devoted to experimental and practical work in the engineering laboratory in illustration of the lectures.—A course of about twenty lectures on mechanical engineering will be given by Prof. Hudson Beare, at University College, on Friday evenings from 7.30–9.30, commencing Friday, October 13.—A special course of lectures on alternating currents will be given by Prof. Wilson, at King's College, on Monday evenings, at 6.30 p.m., beginning October 9.—The following courses have been arranged to be held under the direction of Prof. Ramsay, at University College. In both of these courses the work will be *original*. (*a*) A course of twelve lectures on sewage and its purification, by Dr. Samuel Rideal, on Mondays, at 5.30 p.m., commencing November 6. (*b*) A course of lectures on spectroscopy and spectrography will be delivered by Mr. E. C. C. Baly.

## SCIENTIFIC SERIAL.

*Wiedemann's Annalen der Physik und Chemie*, No. 8.—Limits of the solid state, by G. Tammann. Experiments on a number of organic bodies show that even when the heat of fusion is very nearly or accurately zero, the difference between the specific volumes of the liquid and the crystals is considerable.—Magnetic properties of hematite, by A. Abt. The maximum magnetic moments of three equal prisms, of pyrrhotite, hematite and magnetite respectively, were found to be in the ratio of 1 to 2·356 to 3·237. Pyrrhotite shows the smallest magnetisation in comparison with its percentage of metallic iron.—The blue steam-jet, by A. Bock. A sky-blue colour is imparted to a steam-jet by sending through it a current of air saturated with hydrochloric acid. The jet, as regards colour, polarisation and diffraction, shows a close analogy with the atmosphere.—Resistance of alloys, by R. H. Weber. To measure the resistance of brittle alloys, like those of zinc and copper in which the zinc preponderates, the author employs the alloy in the form of thick plates or cylinders. A magnetic needle is made to vibrate over the plate, and its logarithmic decrement is directly proportional to the conductivity of the alloy. The method has the further advantage that the substance need not be exposed to much mechanical working, such as is involved in wire-drawing. Work consumed in a spark gap, by E. Riecke. In a 40-plate Toepler machine, the work consumed with a gap of 2 cm. is 1·64 watts per turn, and with a gap of 6 cm. it is 5·27 watts. A further increase of the width of gap diminishes the work of the spark.—Pressure in the spark, by E. Haschek and H. Mache. By noting the increase of pressure in a vacuum tube on sparking, and the volume of the spark itself, the authors arrive at an estimate of the pressure within the spark. It is of the order of fifty atmospheres.—Potential gradient at the anode, by C. A. Skinner. The drop of potential from the anode to the adjoining gas during a low discharge is about 20 volts. This increase is to about 40 volts within a distance of a few millimetres from the anode; but there is no potential gradient within the thin luminous layer immediately adjoining the anode. The greater the drop of potential at the anode, the less is the potential gradient in the anode light.—A radio-active substance, by E. de Haën. By extraction from a large quantity of uranium ore, the author has obtained substances which possess the properties ascribed to "radium" in an extraordinary degree. One preparation exhibits all the properties of Becquerel radiation, and, in addition, possesses the property of being strongly luminous. This luminosity is rapidly impaired by moisture, and can only be restored by melting the substance in the oxyhydrogen blowpipe.

## SOCIETIES AND ACADEMIES.

### PARIS.

**Academy of Sciences**, September 18.—M. Maurice Lévy in the chair.—Variations of volume in Portland cement resulting from setting and hygrometric state, by M. Considère. The expansions of cement prisms immersed in water were studied for a period of over two months, comparisons being made between loaded and unloaded prisms. The expansions increased very regularly, and were much less with a mixture of cement and sand than with pure cement. Owing to this gradual expansion, metal plates holding cement under water may be submitted to much greater stresses than has been hitherto supposed.—On the development of a holomorphic function at the interior of a contour in a series of polynomials, by M. Renaux.—On some experiments designed to confirm Ampère's hypothesis relating to the direction of the elementary electromagnetic action, by M. W. de Nikolaiève.—On Egyptian pottery, by M. H. Le Chatelier. Analyses of five different specimens of Egyptian pottery are given, together with a reproduction of the microscopic appearance of two of them.

THURSDAY, OCTOBER 5, 1899.

## BERTHELOT'S AGRICULTURAL CHEMISTRY.

*Chimie végétale et agricole.* Par M. Berthelot. Four volumes. Pp. xvi + 511, vi + 441, vi + 517, vi + 528. (Paris: Masson, 1899.)

THE ancient Château de Meudon, Seine-et-Oise, which was left in ruins at the end of the war of 1870, was thirteen years later converted into an agricultural experiment station by the French Government, and permanently attached to the Professorship of Organic Chemistry in the Collège de France. In the four bulky volumes now before us, the professor, M. Berthelot, has brought together an account of the various investigations carried out at the station between 1883 and 1899, under his direction, with the assistance in many cases of M. G. André. Besides these reports, the volumes contain an account of several earlier investigations by M. Berthelot. We have in fact brought before us the whole of his investigations on plants, soils and various cognate matters, carried out during the last forty years.

Agricultural chemists will heartily welcome the publication in such a convenient form of this great mass of original investigation. M. Berthelot is well known as a first-class man of science, and as one of the most prolific and versatile workers of the present age. The new ideas he has brought forward concerning many obscure points in agricultural chemistry will be highly valued. Nevertheless, those acquainted with the peculiarities of M. Berthelot's work will not be surprised that a cautious critic is unable always to accept the conclusions to which he has apparently too easily arrived. The more startling and novel are the conclusions brought before us, the more thorough and unmistakable ought surely to be the basis of fact on which these conclusions are built. A few experiments, relating to only a part of the facts in question, must fail to carry conviction when new laws are propounded, or we are asked to surrender as a mistake views previously arrived at after much patient research.

It will be gathered from what has just been said that the papers in the volumes before us are of unequal value. All the investigations are indeed highly suggestive, and no experimental investigator would desire one of them to be omitted; but students of agricultural chemistry will not unfrequently find it advisable to examine with much care the evidence brought forward before accepting all the conclusions of the author.

That we may do no injustice to the book we will, in the first place, call attention to the very valuable investigation upon the nature and properties of humus, which occupies more than one hundred pages in the fourth volume. The elucidation of the chemical nature of humus has been regarded as an almost hopeless problem by the ordinary agricultural chemist. Berthelot has brought to bear upon the subject the methods and conceptions of modern organic chemistry, and his work has resulted in a considerable increase to our knowledge.

Berthelot has carefully studied the composition and properties of the simple nitrogen-free humus obtained by boiling sugar with hydrochloric acid. It appears to be a mixture of a condensed anhydride and hydrate, the simplest expression for the former being $C_{18}H_{14}O_6$. It swells up in water, forming a colloid body. It absorbs a considerable quantity of alkali from an aqueous solution. One third of the potash or soda thus absorbed is permanently retained in a practically insoluble condition after long washing with water. Placed in contact with ammonia an insoluble amido-compound is produced, from which ammonia is not recovered by boiling with magnesia. The oxidation of humus under the influence of light, and its more rapid oxidation in the presence of alkali are also studied. The heat relations of the principal reactions have also been ascertained. All this is fundamental work of very great importance, and throws much light upon the behaviour and functions of humus in a soil.

The natural humus in soil is also studied, and the action of acids and alkalis upon it investigated. The gradual formation of ammonia when the nitrogenous humus of soils is boiled with weak acids, soluble nitrogenous compounds being simultaneously produced, is pointed out as in full agreement with the assumed amido nature of the humic matter. The humus of soils is, however, a very complex substance; it may contain a very distinct amount of sulphur, and even phosphorus, in a state of organic combination. It will certainly be a novel fact for most agricultural chemists to hear that a soil may yield 0·183 per cent. of phosphoric acid when boiled with strong hydrochloric acid, 0·222 per cent. when the silica has been entirely removed by hydrofluoric acid and 0·292 per cent. when the soil is burnt in oxygen gas and the products retained by sodium carbonate. The excess obtained by combustion in oxygen is regarded by Berthelot as representing the phosphorus in organic combination. This part of the subject clearly requires much further investigation. Phosphorus, if present, is possibly a survival of the nuclein occurring both in the animal and vegetable kingdom.

We take our next example from one of the less satisfactory of M. Berthelot's investigations, in which the evidence brought forward seems quite insufficient to warrant the conclusions which he seeks to establish.

He has determined the quantity of nitrates present in certain plants, and has conceived the idea that plants have the power of producing nitrates abundantly in their own tissues. This assumption, if proved, would clearly furnish an entirely new departure in vegetable physiology One would have thought that to establish such an hypothesis the plant would have been grown in a medium supplying no nitrates; any appearing in the plant would then clearly be due to the work of the plant itself. M. Berthelot makes no such experiment. To establish his position, he grows the plant (borage or *Amaranthus*) in the open field, without any knowledge of the quantity of nitrates produced in the soil during the season of growth, and without taking into account the upward movement of subsoil water containing nitrates during the dry summer of his experiment. He is satisfied by ascertaining that on September 25 a square foot of soil contained only about 1/20 of the quantity of nitrate contained in the plant pulled up from it, and that a similar bulk of soil taken at the beginning of the season, from another part of the

AA

field, contained a similar quantity of nitrate to that found in the exhausted soil around the plant at the end of the season. The next year he finds that the soil of the field, when deprived of vegetation, doubled its contents in nitrates between June 4 and "the end of the season"; but this rate of increase was insufficient to account for the nitrates found in the crop the *previous year!* Finally, to prove that the plant contains a nitrifying agent, a single experiment is made by introducing a fragment of the stem of *Amaranthus* into a flask containing 300 grams of sterilised and exhausted soil. At the end of eleven weeks six milligrams of saltpetre were found in the soil. A blank experiment, made with soil only, was for some reason only continued for six weeks.

Data such as these are quite insufficient to convince a critical reader. Our confidence in the investigation is not increased by reading that the growth of a *single* crop in the field diminished the nitrogen in the soil from ·275 to ·173 per cent., and the potash of the soil in the neighbourhood of the roots from ·64 to ·47 per cent. Nor by remarking that the same figures for nitrates in the soil are first quoted as kilograms, and are afterwards always spoken of as grams.

The whole of the first volume is occupied with an account of investigations on the fixation of atmospheric nitrogen by soil and plants. M. Berthelot has been a pioneer in this branch of inquiry. The peculiar function of the organism forming the nodules on the roots of leguminous plants is now universally recognised. A similar case of symbiosis between a nitrogen-assimilating organism and certain algæ is also well known. Not so well known is the isolation of a bacillus from the soil by Winogradsky, which when supplied with sugar, and protected from the action of oxygen, is capable of assimilating atmospheric nitrogen. This organism succeeds in assimilating nitrogen from ordinary air when it is associated with ærobic organisms which appropriate the oxygen, and thus produce conditions suitable for the growth of the bacillus assimilating nitrogen.

Both in the case of the reaction in the leguminous rootlets and algæ, and in the case of the reaction *in vitro*, studied by Winogradsky, we have a clear indication of the source of the chemical energy which accomplishes the difficult task of bringing nitrogen into a state of organic combination; in every case we have carbohydrates abundantly present, and in Winogradsky's experiments we have a demonstration that the quantity of sugar fermented is a measure of the quantity of gaseous nitrogen assimilated.

With this principle before us we should suppose that a soil entirely destitute of vegetation could fix nitrogen only at the expense of its own organic matter; carbon would, in fact, be lost in the operation of fixing nitrogen. If, on the other hand, certain green algæ or leguminous plants were present, fixation of nitrogen might be accompanied by an actual gain of organic matter.

According to Berthelot's experiments, soils destitute of visible vegetation may gain large quantities of nitrogen when exposed to air. Even subsoils of argillaceous sand or clay, containing mere traces of carbon or nitrogen, are capable of gaining considerably in nitrogen when exposed to air. From an agricultural point of view, the quantities of nitrogen fixed are very considerable. Layers, 7 inches deep, of three surface soils from Meudon, fixed in 11 weeks from 70 lbs. to 130 lbs. of nitrogen per acre, quantities equivalent to 6–11 tons of farmyard manure. If this enrichment of soil by mere exposure to air is a fact, we shall be very anxious to know what are the precise conditions and limitations of such a beneficial action. Scientific agriculturists will be loath to admit that the exposure of a soil uncovered by vegetation tends to its permanent enrichment; the process of weathering tends, on the contrary, to the exhaustion of soil capital, and not to an increase of nitrogenous organic matter.

Berthelot's trials of various organisms yielded results of a similar favourable character. Out of seven organisms tried five produced an active fixation of nitrogen. The composition of the medium was apparently indifferent, for a mixture of certain bacilli from soil with kaolin determined an increase of 32 per cent. of the original nitrogen in one case, and an increase of 150 per cent. in another. Among the organisms fixing nitrogen, Berthelot includes the common mould *Aspergillus niger*.

In the last section of this volume Berthelot describes experiments which lead him to the conclusion that the natural electrical conditions, both of soil and plant, aid in bringing about the fixation of nitrogen from the air.

It is to be regretted that the large amount of work contained in these volumes is not of a more thorough and definite character, but we are very thankful that the investigations have been published. R. W.

## OUR BOOK SHELF.

*Bird Life in an Arctic Spring; the Diaries of Dan Meinertzhagen and R. P. Hornby.* Edited by Mrs. G. Meinertzhagen. Pp. iii + 150. Illustrated. (London: Porter, 1899.)

A PATHETIC interest attaches to this volume, as being practically a memorial to a most promising and talented young ornithologist, whose life was unhappily cut short almost at the outset of his career. The late Mr. D. Meinertzhagen was essentially a lover of bird-life, and thus a naturalist in the very best sense of that somewhat abused word. But he was much more than this, being an artist of great talent, whose sketches and etchings of birds form some of the most beautiful delineations of feathered life it has been our fortune to see. In addition to those illustrating the text itself, nearly thirty of these talented sketches have been photographically reproduced as an appendix to the present volume, and serve not only to enhance the general interest of the latter, but likewise to convey an excellent idea of the artistic capacity of the author of the journal which constitutes its main claim to attention.

As we gather from the preface, the book is mainly intended for private circulation, and only a limited number of copies are offered to the general public. On the whole, the editor has exercised a wise discretion in endeavouring to preserve the journal of her son as much as possible in its original form, although it must be confessed that a little fuller supervision on the part of a trained ornithologist than has been permitted would have been advantageous in a few instances.

The journal is divided into two portions, the first and longer by Mr. Meinertzhagen, and the second by his companion Mr. Hornby. The trip to Lapland, of which these form the chronicle, was undertaken in 1897; and the journal of the originator breathes out the enthusiasm of an ardent bird-lover. The two companions appear to have visited spots to which few if any Englishmen

have penetrated since Wolley's time; and in collecting eggs they suffered almost from *embarass des richesses* on account of the numbers that were brought in by the natives. One of the objects of their desire was to obtain a clutch of Smew's eggs, but it was not an easy matter to identify these without some of the down from the nest. At length they succeeded in obtaining what they thought were the right eggs; and their acumen was confirmed on arrival in England by the identification of the specimens from the down.

A section of the volume is also devoted to an account of the magnificent collection of raptorial birds maintained by the late author of the first journal at his father's seat, Mottisfont Abbey, Romsey. This collection, which is stated to be one of the finest in England, is still maintained; and the account shows how it is possible to keep such splendid birds in perfect condition. Altogether, the bird-lover will find much to interest him in this charming little volume. R. L.

*Progressive Lessons in Science.* By A. Abbott, M.A., and Arthur Key, M.A. Pp. xix + 320. (London: Blackie and Son, Ltd., 1899.)

THIS book consists of two parts—the first, by Mr. Abbott, dealing with the non-metallic elements found in animal and vegetable substances; the second, by Mr. Key, on the detection and distribution of the elements in animal, vegetable and mineral substances. The former part contains a course of experimental work in chemistry of a kind with which many text-books have made us familiar. All that need be said of it is that most of the experiments are suitable for performance in the laboratory by beginners in chemistry, and that the book will assist the progress of rational methods of science teaching. With regard to the second part, though the plan has something to commend it, the execution is open to criticism. Mr. T. G. Rooper, who generously endeavours to assist the volume by his introduction, remarks upon the idea to which we refer. "The most original feature in the book is the set of experiments which illustrate the composition of food-stuffs. Starting with a table of the chief constituents of the blood, the author proves the presence of each by the use of an ingeniously-devised test. He then traces each constituent through animal life to the vegetable life on which animal life is supported, and thence to the soil from which the plant derives it, and finally to the rock, by the disintegration of which the soil is formed." There are several grave objections to this method of procedure as it is here presented. Students are *told* the tests which have to be applied to detect different substances, hence the experiments are not in advance of the test-tube practice which is fast giving place to more intelligent practical instruction. Moreover, the object of the experiments is too complicated to be of real educational value to beginners; and, finally, very few students have the time to do so much experimental work. Originality in text-books is a very commendable characteristic, but the authors should know that practicability is an even more important factor to consider. In its present form the book may be of service to a few teachers of domestic science and hygiene, but we do not think any other useful purpose will be served by its publication.

*De la Méthode dans la Psychologie des Sentiments.* By F. Rauh. Pp. 305. (Paris: Félix Alcan, 1899.)

THIS is a valuable monograph the merit of which is unfortunately partly concealed by a singularly obscure and unattractive literary style. M. Rauh's principal object is to enter a warning against the growing tendency of psychologists to neglect the adequate description of complicated facts, and to corrupt their science in its infancy by excessive reliance upon over-simple metaphysical and psychophysical theories. Psychology, as he well points out, possesses as yet no such simple and universal generalisation as that of the conservation of energy; in the present state of the science any single theoretica generalisation is premature; for the full description of the facts of mental life we need many points of view, each represented by a different tentative hypothesis. Thus the emotions, which form the immediate subject of the essay, may be studied as concomitants of physiological changes in the organism, as embodying a *quasi*-judgment on the part of the organism as to what is beneficial or harmful, as manifestations of the "will to live," or finally as special phenomena calling for independent description and classification. Each of these points of view throws light upon some characteristic of human emotions, and none of them can be neglected in a complete psychology of sentiment. In the course of the argument many one-sided theories, especially that of Prof. James as to the organic concomitants of emotion, receive really trenchant criticism. Like most French writers, M. Rauh is particularly happy in what may be called "psychological diagnosis"; his too rare descriptions of the various emotional "temperaments" are subtle and illuminating. On the other hand, he makes occasional slips which partly vitiate his reasoning. In his deductions from the supposed existence of special "pain-conducting" nerves, for instance, he forgets to allow for the possibility that what the nerve conducts is the special presentative element, the "racking," "stabbing," or "burning" sensation rather than the painfulness of it. Again, he scarcely lays enough stress on the fact that our emotional state at any moment depends, not on isolated sensations, but upon the total complex of our sensations at the moment. And, finally, to the present writer at least, the conception of "psychical forces," of which M. Rauh makes great use, is exceedingly obscure. It is a pity that terminology, which has led to so many confusions, even in dynamics, should be needlessly transported into psychology. A. E. T.

*Histoire Abrégée de l'Astronomie.* Par Ernest Lebon. Pp. vii + 288. (Paris: Gauthier-Villars, 1899.)

THIS book, as its title implies, is not intended as a complete history of the progress of astronomical science from the earliest day, but is devoted to rendering a brief account of the main steps in this progress, and at the same time giving us short biographical sketches of the chief workers in this branch of science. The subject is divided into three parts. The first deals with the ancient period which ends in the middle of the sixteenth century: only eighteen pages are devoted to this portion, so that the reader can rightly conclude that only a very general sketch has been attempted. The second or modern period, extending to the middle of the nineteenth century, commences with the system of Copernicus, and ends with an account of the state of the science at the time of the death of the illustrious astronomer of the Königsberg Observatory, Friedrich-Wilhelm Bessel. The last, or contemporary, period is contained in 125 pages. M. Lebon divides this portion of the book into ten chapters, dealing in each with the progress made in separate branches of the subject. Thus we find first an account of the advance made in celestial mechanics, then the progress in observational astronomy, spectroscopy, geodesy, photography, &c. Each of these reviews is brought well up to date, and contains a good general survey of the progress made. A useful addition to the book will be found in the biographical and bibliographical dictionary which follows this last portion. Besides a small chart of the northern hemisphere, which apparently has little utility in such a book as this, the illustrations include a set of sixteen processed reproductions of portraits of celebrated astronomers. Not only should astronomical readers find this book a welcome addition to their libraries, but those interested in the welfare of this, the oldest, of sciences, will peruse these pages with advantage.

## LETTERS TO THE EDITOR.

*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

### The Intake of Carbon Dioxide—a Correction.

WILL you give me the opportunity of making the following correction in my Presidential Address to the Chemical Section of the British Association.

I stated incidentally that Mr. F. F. Blackman, in his well-known experiments on the intake of carbon dioxide into the two sides of an assimilating leaf, employed air enriched with that gas to the extent of 4 per cent. and upwards.

Mr. Blackman has pointed out to me that in the experiments in question he used air containing only from 1·8 to ·33 per cent., and that since the publication of his earlier results he has still further reduced this amount. In fact he is of the opinion that his method is applicable to the measurement of the intake of carbon dioxide of even a much greater degree of dilation.

The error was an inexcusable one on my part, but does not affect the main argument that the natural rate of intake cannot be directly deduced from experiments in which the carbon dioxide content of the air materially departs from the normal amount 0·03 per cent. HORACE T. BROWN.

52 Nevern Square, Kensington, S.W., September.

### Geological Time.

IN his Presidential Address to Section C at Dover, Sir A. Geikie has offered a bold challenge to Lord Kelvin and those who agree with him by calling upon them to give due weight to geological phenomena in forming an estimate of geological time. Permit me to say what I think about it.

It seems to me probable that, when the grand idea of the universal dissipation of energy had occurred to Lord Kelvin, he saw that the principle must be applicable to the earth, and that, if the law of conduction of heat could be used, he might from it obtain an estimate of the world's age. He then instituted his important experiments to determine the conductivity of rocks *in situ*, and found the value 400 (more or less), the units being a foot a year, and a degree Fahr. But it was necessary, for his calculation to succeed, that he should assume the earth to be solid. If I do not misjudge him, I think he then sought for arguments to prove this point. Now, I cannot but think that the proofs of solidity on which physicists rely are by no means convincing; and if the earth is not solid, Lord Kelvin's estimates are without foundation. Moreover, it is not sufficient that the earth should be solid at the present, to which these proofs refer, but it needs to have been so from the beginning of the time to which his estimates go back.

Prof. G. Darwin, in his book on the tides (p. 237), has done me the honour of referring to my "Physics of the Earth's Crust" as if I am an arch-heretic on this question of solidity. Whether my arguments are beneath notice, or whether there is a difficulty in answering them, I do not know; but they have never been refuted, while they are held to be of decided force by some geologists, and among these by the Indian Geological Survey.

Harlton, Cambridge, September 25. O. FISHER.

### The Terrestrial Gegenschein.

I DO not know whether the phenomenon I am about to describe has ever been noticed. The circumstances under which it is noticeable must occur rarely. They are these:—

I spent some time of the summer of 1898 on an isolated mountain peak, surrounded by lower mountains whose sides were densely wooded. The result was that near the time of sunset the shadow of my own mountain peak was visible on a mountain side which might have been three or four miles distant. One evening I amused myself by watching the shadow of the peak as the sun was descending. My attention was attracted by an illumination in the direction opposite the sun so strikingly resembling the astronomical gegenschein, that at the first glance I saw in it an explanation of the latter. It consisted of a somewhat bright glow, which might be a degree or two in diameter, but which shaded off by such imperceptible gradations that a definite extent could not be assigned. A little study, however, showed an explanation. As I have said, the mountain on which the glow was seen was densely wooded. In such a case the shadows of those leaves and branches which the sun's rays first reached fell upon the interior foliage and obscured it. But an observer looking from the exact direction of the sun will see through the foliage as far as the sun's rays extend. In other words, the visible surface on which he is looking will be entirely illuminated by the sun's rays, whether this surface is formed of the outer strata of foliage or of a strata ever so far inside, which can be seen only through the crevices in the outer stratum. The shaded interior will be entirely invisible to him. But if his point of view is in a direction ever so little oblique, he will see only the outer foliage illuminated, while more or less of the interior foliage which he sees will be in the shadow. Thus the region exactly opposite the sun will be seen in its full brilliancy, while the neighbouring region will be a mixture of light and darkness. At a distance of several miles this compound of light and darkness will be fused into a single half-shade, strongly contrasting with the full brilliant light of the opposite point.

It is clear enough that we cannot have such a state of things as this in the case of the astronomical phenomena. Yet the phenomenon seems to be of sufficient interest to warrant its being placed on record. S. NEWCOMB.

### The Cause of Undercurrents.

IN NATURE of August 3, p. 316, is given a letter from Rear-Admiral Sir William Wharton, in which he states that he is diametrically opposed to my opinion about the double currents in the Straits. He says that "Admiral Makaroff considers that difference of density of the water is the primary, and, indeed I gather he thinks, the only cause of these opposing currents; but he brings no evidence beyond theoretical considerations in support of his belief"; further, in his letter, Admiral Wharton refers particularly to the double current of the Bosporus, of which I spoke in my lecture at the Royal Society of Edinburgh. I cannot leave unnoticed remarks from so distinguished a hydrographer, who, during his long work, has contributed so much to the advance of science. My researches about the Bosporus are published only in Russian, in a book named "On exchange of water between Black Sea and Mediterranean" (St. Petersburg, 1885). Should Admiral Wharton know my language, he would easily come to the conclusion that my opinion about double currents in the Bosporus are based upon the observations made in 1881 and 1882. I then invented an instrument for measuring the current at different depths, and gave the name of "fluctometer" to it. The instrument consists of a propeller revolving on a horizontal spindle. A bell is attached to the propeller, and at every revolution of the propeller it strikes twice. As water is a very good conductor of sound, the number of revolutions could be counted through the bottom of the ship (provided the ship is not sheeted with wood) at all depths to which the instrument was lowered (40 fathoms). I used to anchor in the middle of the Bosporus for a couple of days at a time, and make a series of observations every two hours. In order to obtain more detailed data, I used to take the samples of water from the same depth to which the fluctometer was lowered. Twice I used to go along the Bosporus from the Black Sea to the Marmora Sea in order to learn in what depth is the limit of two currents. In volume xxii. of the *Proceedings* of the Royal Society of Edinburgh, Plate I. shows a position of the limit of two currents, mean velocity of both currents, and specific gravity of water. In Plate II. is given a sketch of my "fluctometer."

I am sorry that the limits of this paper do not allow me to give particulars of my observations, but I believe some of my deductions, worked out from direct observations, would be interesting to English readers.

Mean velocity of the upper current, $3\frac{1}{4}$ feet per second. It varies from 0 to 10 feet per second in certain places.

Velocity of the upper current diminishes with every fathom of depth.

Limit between two currents close to the Marmora Sea is at 11 fathoms. It gradually goes down to 27 fathoms close to the Black Sea. Limit between two currents is influenced by winds and by barometrical pressure, but not very much.

Lower current has close resemblance with the river. Its velocity does not vary very much. We never found anywhere

lower current less than 1·84 and more than 3·22 feet per second. Mean velocity of the under current was 2·32.

The upper current does not everywhere occupy the full breadth of the strait. It flows in some places under the north coast of the strait, and in other places under the south coast. Lower current also does not flow over the whole breadth, and occupies a certain part of the bed of the strait. In my book I give a chart of the Bosporus, where I show direction of the upper and lower currents. A glance at that chart will show that there are places where both currents can be found, and there are places where the instrument will show the existence of only one of them, and in some places the explorer will not find either upper direct current or under current.

Difference of level of Black and Marmora Seas, calculated from difference of specific gravity of water, is 1 foot 5 inches. Mean specific gravity of water $\left(S\frac{17\cdot5}{17\cdot5}\right)$ entering from the Black Sea into the Bosporus is 1·0140. Mean specific gravity of water entering from the Marmora into the Bosporus is 1·0283.

By upper current pass 370,000 cubic feet per second. By lower current pass 200,000 feet per second. Difference between these two figures being 170,000 feet per second is due to the excess of fresh water in the Black Sea.

I hope that after reading these figures and deductions Admiral Wharton will change his opinion, and come to the conclusion that my idea about double current in the Bosporus is based, not only on theoretical considerations, but also upon direct measurement.

Admira Wharton expresses also his opinion about double current of the strait of Bab-el-mandeb, and says that "there are none of the differences of specific gravity." I may be permitted to refer to my other book, "Le Vitiaz et l'Ocean Pacifique," where I give (p. 136, plate xxvii.) specific gravity of the strait of Bab-el-Mandeb measured by myself. Examination of figures given there by me shows that there is a difference of specific gravity which produces double current in that strait.

Nobody can deny that the wind has a great influence upon the movement of surface water; but I hope that Admiral Wharton will agree with me that differences of specific gravity has also some influence upon the circulation of water in the seas generally and in the straits particularly. S. MAKAROFF.

*Ermack*, Newcastle-upon-Tyne, September 23.

## Movement of Sea-Gulls with a Coming Change of Weather.

THE suggestion that sea-gulls may have some meteorological sense would be best tested by inquiry as to whether there was, at the time of their westward flights, observed by your recent correspondents, any other possible motive for their journeys; and particularly what food was available in the Channel at the time.

Neither of your correspondents needs to be told that every sea-gull is a semaphore to every other sea-gull in sight of him, nor that one gull "working on" fish will presently be surrounded by others from all sides.

In clear, fine weather the news of abundant sprats would be passed along the Channel in this way, faster than by military signallers, and answered by a concentration of gulls much speedier than any possible to troops.

Moreover these birds, and vultures, as I know from repeated observation, do not merely *follow each other* round the headlands. If a gull in a bay sees another gull hurrying from the offing into the next bay, he does not fly round the headland between, but rises over it, well knowing that from the upper air he will see whatever hurried the outer gull. As he does so his motions will be observed, and probably acted on by others further within the first bay; and if food be failing in the Thames, and abundant off the Wight, there will be plenty of gulls flying across Kent, and some across even Surrey. Here in Chelsea I seldom see large gulls on the river. But it is a common enough thing to see them flying high overhead to the south-westward.

Westerly and south-westerly gales are so common in the Channel that neither beast nor bird can make any movement without a good off-chance of finding one on his way. It has to be remembered that most of our migratory sea fish are apt to run *up* Channel in the warm half of the year, so that the message, "Plenty of fish on the surface," is probably most often passed from west to east.

We shall, I think, need a good many simultaneous observations at various points and of various matters before we make it even probable that sea-gulls can foretell a south-west wind, and will then go to meet it. They cannot eat it; and, if strong, it will give them little leave to eat anything else; so the motive is not apparent. W. F. SINCLAIR.

102 Cheyne Walk, Chelsea, S.W., September 22.

## On the Use of the Fahrenheit Scale for Observations on Sea Temperatures.

IN addition to the Fahrenheit scale being so much more practical for observation in meteorology than the Celsius, allow me to point out that in observations for ocean temperature it is even more so, and especially when we come to deal with observations taken in the polar regions. Here with the Fahrenheit scale we have never to deal with a minus reading at all; whereas with the Celsius scale it is a constant change from plus to minus and minus to plus. This introduces a source of very serious error both in observation and calculation, besides adding to the work, and therefore the cost of working up results. The boon of never having to think of a minus in such work is not to be lost sight of for the sake of fashion. As one who has taken part in extensive observation and calculation work at Ben Nevis Observatory, on board ship, and in connection with the Scottish Fishery Board, I would also urge the use of the Fahrenheit scale for meteorological observations on the same grounds as Mr. J. Y. Buchanan and Mr. H. Helm Clayton.

Joppa, Edinburgh, September 25. WILLIAM S. BRUCE.

## Cave Shelters and the Aborigines of Tasmania.

I HAVE just received news from Mr. J. B. Walker, of Hobart, of the discovery of some interesting relics of the aborigines of Tasmania. Mr. Walker accompanied Mr. R. M. Johnston, the Government Geologist, on an expedition in search of some remains of Tasmanians, and the party were rewarded by finding a hitherto unknown so-called quarry where the natives manufactured some stone implements, also a cave which showed considerable evidence of having been used by the aborigines, as well as a tree notched by them for climbing purposes. The sandstone cave or rock shelter i situated in Hutton Park, near Lovely Banks. The quarry is situated at Coal Hill, two miles north of Melton Mowbray, about 40 miles N.N.W. of Hobart, and 1100 feet above the sea-level.

The discovery of this quarry makes the tenth known quarry used by the aborigines, and the first mention of their use of cave or rock shelters. H. LING ROTH.

Halifax (Yorks.), September 27.

## The Darjeeling Disaster.

UNUSUALLY large seismograms were obtained in the Isle of Wight on September 3, 10, 17, 20 and 23. The first three refer to disturbances originating in Alaska. The fourth refers to disasters in Asia Minor, and the last to an earthquake having an origin as distant as Japan. Since the 23rd in the Isle of Wight, and I believe also at Kew, not the slightest movement has been recorded. The inference is that the great earthquakes reported as having taken place at Darjeeling on the night of September 25–26 are at the most small and local, and are not likely to have been recorded outside the Indian Peninsula. It is extremely likely that the tremors noticed in Darjeeling were due to landslides, and seismic phenomena were entirely absent. J. MILNE.

Shide Hill House, Shide, Newport, Isle of Wight, September 27.

## Lectures at the Royal Victoria Hall.

I SEE in your issue of September 21 (p. 513) the statement that I am to lecture at the Royal Victoria Hall on "Photographs taken in the dark." I beg to say that the title I gave for my lecture was "Pictures taken on a photographic plate in the dark." I suppose the authorities at the Hall consider the titles identical. I do not. W. J. RUSSELL.

St. Ives, Ringwood, Hants, September 26.

### Vole.

I think Nature should take note of a short article by Prof. Skeat in the number of *Notes and Queries* for September 16, wherein he points out that *vole* is corrupt Norwegian for field, and that therefore a water-vole is a water-field, a field-vole a field-field, and a bank-vole a bank-field.

Exeter. James Dallas.

## THE INVESTIGATION OF THE MALARIAL PARASITE.

Pending the arrival here of Major Ross and part of the Malaria Expedition connected with the Liverpool School of Tropical Diseases, which is expected about October 7, we may, from information already to hand, forecast some points in his report without in any way detracting from the interest with which it will be received.

In the issue of this journal for September 7 we recorded the fact that a species of Anopheles was found to be concerned in the transference of all the forms of malaria. In the barracks of Wilberforce, a suburb of Freetown, Sierra Leone, out of four hundred men there was a daily average of forty ill in hospital with all three forms of malaria. The place seems to have been infested with mosquitoes, but only the genus Anopheles was found, and of those examined one-third were found to contain zygotoblasts.

In searching for the haunts of the Anopheles larvæ the members of the expedition found them chiefly in small stagnant pools in which green algæ were growing. The larvæ appear to live upon this, for larvæ hatched from eggs did not grow unless they were given some of the algæ to feed upon. They infer that the conditions under which algæ will grow, namely, in stagnant puddles, are the same as those under which Anopheles larvæ will hatch out and thrive; the larvæ of Culex were found in every receptacle for stagnant water, even in old sardine tins. Stagnant puddles are only found during the rains on low-lying ground, and near a stream or spring, from which they can be replenished in the dry season. So far, only one experiment on the action of kerosene oil on larvæ has been reported; one drachm of the oil was poured on the surface of a pool of water of about a square yard in area, and all the Anopheles larvæ it contained were found dead after six hours.

Ross considers the Anopheles to be the genus concerned in propagating malaria, and seems to rely on being able to exterminate them from a locality to free it from the disease.

Koch (*Erster Berichtüber die Thätigkeit der Malaria Expedition*, April 25 bis August 1, 1899) found *Culex pipiens* to be concerned in propagating malaria in Tuscany, but to a lesser extent than the Anopheles. The German Commission find that the parasite requires a temperature of 80° F. to develop in the mosquito, and it is only found in these insects during the summer months. At the commencement of the hot weather the mosquito draws the parasite with the blood from a patient who has a relapse. Human beings with the parasite in their blood they consider to be the connecting link during the nine months of the year when the temperature does not allow of the parasite developing in the mosquito: they think relapses can be stopped by the use of quinine; so by this means it would become possible to stamp out the disease.

It is evident we want a large series of observations made in different parts of the world, for, if the genus Culex can propagate the disease, it would be almost impossible to exterminate these if they breed wherever water lies. On the other hand, should relapses of fever be prevented by a proper use of quinine, malaria would not be stamped out in countries where the temperature is sufficiently high all the year round to allow the parasite to develop in the mosquito.

## MR. PERCY S. PILCHER.

Many of our readers who were acquainted with Mr. Percy S. Pilcher, and others who have only heard of him through his great enterprise and keenness in constructing and using aërial machines, will be very sorry to hear that his accident on Saturday last has proved fatal, and that he died at 2.40 on Monday morning.

Mr. Pilcher, during the last few years, had been making a considerable number of experiments with the object of constructing a soaring machine which would propel itself. The writer of this note was present at one of his trials in August 1897, at the time when he was at work in designing a small light engine for propelling his machine, and communicated to this journal an account (with illustrations from photographs) of his experiments on that occasion (Nature, vol. lvi. p. 344).

Like his forerunner Otto Lilienthal, Mr. Pilcher has come to the same sad end, and now his name must be added to that already long list of pioneers in aërial navigation.

The experiments causing the fatality took place on Saturday last at Stanford Hall, the seat of Lord Braye, near Market Harborough.

We gather from the *Times* that after several ineffectual attempts to start, a signal was given about twenty minutes past four, and Mr. Pilcher rose slowly in the machine until he had travelled about 150 yards, and had risen to a height of about 50 feet or 60 feet. Then a sharp gust of wind came and the tail of the apparatus snapped. Instantly the machine turned completely over and fell to the earth with a terrible thud, Mr. Pilcher being underneath the wreckage. His devoted sister was one of the first to reach the scene of the accident. Mr. Adrian Verney-Cave, Mr. Everard Fielding, and Dr. Stuart, all friends and companions of Mr. Pilcher, removed him from the machine and found that he was unconscious. Raising his left leg it was discovered that it was fractured above the knee. Mr. Pilcher was carried to his room in the house, and Dr. Stuart and Dr. Nash carefully examined him, another surgeon being summoned by telegraph from Rugby.

W. J. S. L.

## NOTES.

Prof. Simon Newcomb has been elected president of the recently established Astronomical and Astrophysical Society of America. The secretary is Prof. G. C. Comstock.

The seventh International Geographical Congress began a series of successful meetings on Wednesday, September 27, at Berlin. Papers have been read by, among others, the Prince of Monaco, on his Greenland Deep-sea Expedition, and Dr. Nansen, on "The Hydrography of the Polar Sea." At one of the sittings of the Congress a telegram was read from Mr. H. J. Mackinder, the Reader of Geography at Oxford, announcing that he had succeeded in reaching the summit of the hitherto unscaled Mount Kenia in British East Africa, and that some fifteen glaciers were found upon the mountain. It will be remembered that Mr. Mackinder left England in June last in charge of an exploring expedition.

A buoy bearing the inscription "Andrée's Polar Expedition," found on the north side of King Charles Island, north-east of Spitsbergen, 80° latitude and 25° east of Greenwich, on September 11, has been brought to Stockholm and there opened in the presence of several experts and Ministers. It was found to be the so-called "North Pole buoy" which the explorer was to have dropped when passing the North Pole. So far as the examination extended no message from the explorer was

revealed. Prof. Nathorst declared that the buoy could not have been carried from the Pole to King Charles Island, and Captain Svedenborg was of opinion that it had been thrown out empty. A search is, it is stated, to be made next year at King Charles Island.

A MARBLE bust of Prof. Emil Du Bois Reymond has been presented to the Physiological Institute of the University of Berlin by the professor's widow.

THE new Paris Institute of Biological Chemistry, facing the Pasteur Institute, towards the erection and endowment of which Baroness Hirsch gave 80,000*l.*, is now, so far as the exterior is concerned, completed.

PROF. R. BURCKHARDT, of Bâsle, and Prof. V. Uhlig, of Prague, have been elected members of the Academy of Sciences of Halle.

THE death is announced, at the age of forty-five, of Dr. Kowalowsky, professor of hygiene in the University of Warsaw, and of Canon Carnoy, professor of the natural sciences at the University of Louvain.

IN connection with the Glasgow Lecture Association a special science lecture will be given to school children during the Christmas holidays by Prof. McKendrick, F.R.S.

PROF. GEORG STEINDORFF, the director of the Aegyptologische Sammlung at Leipzig, has, it is stated, obtained leave of absence for six months to enable him to undertake a scientific journey to Africa.

DR. L. A. BAUER, of the U.S. Coast and Geodetic Survey, is at present in Europe for the purpose of inspecting various magnetic observatories and the comparison of the Coast and Geodetic Survey instruments with observatory standards.

THE announcement is made that Mr. W. H. Twelvetrees has been appointed geologist to the Government of Tasmania. During recent years Mr. Twelvetrees has devoted considerable attention to the geological formation of Tasmania, with special reference to mining operations, and has been a frequent contributor of papers to the Australian Institute of Mining Engineers and to the Royal Society of Tasmania.

THE Corporation of Glasgow has just appointed Dr. R. M. Buchanan bacteriologist to the city. He will devote the whole of his time to the duties of the office, and a laboratory has been assigned to him in the Sanitary Chambers.

IT is announced in the *Pioneer Mail* that Mr. Douglas Freshfield has arrived at Darjeeling, accompanied by two Swiss guides, intent on exploring the great snowfields of Kinchinjunga.

THE tenth International Congress of Hygiene and Demography will be held in Paris from August 9 to 17, 1900.

THE second International Congress on Hypnotism will be held in Paris from August 12 to 16, 1900, under the presidency of Dr. Jules Voisin. The questions proposed for discussion are: (1) The formation of a vocabulary concerning the terminology of hypnotism and the phenomena connected therewith; (2) the relations of hypnotism with hysteria; (3) the application of hypnotism to general therapeutics; (4) the indications for hypnotism and suggestions in the treatment of mental disease and alcoholism; (5) the application of hypnotism to general pædagogy and mental orthopædics; (6) the value of hypnotism as a means of psychological investigation; (7) hypnotism in relation to the (French) law of November 30, 1892, as to the practice of medicine; (8) suggestion and hypnotism in relation to jurisprudence; (9) special responsibilities arising from the practice of experimental hypnotism.

IN compliance with the request made by Russian men of science to the Russian imperial authorities, the scientific exploration of the coast-line of the Pacific in the Far East is to be undertaken. It has been arranged that a distinguished zoologist and member of the Imperial Russian Geographical Society shall undertake the exploration at the cost of the Society, in conjunction with the Ministry of Agriculture. The expedition intends to make investigations with a view to classifying the marine fauna and flora on the coast of the Russian territory, and the conditions of zoological life will also be investigated upon the Liao-Tong peninsula, and in the adjacent regions of Manchuria and Korea. The period for these investigations has been fixed at two years, and the cost of the expedition is estimated at 12,000 roubles. The Geographical Society has promised to make a grant of 7500 roubles towards this sum, and the Ministry of Agriculture and Imperial Domains will contribute the remaining 4500 roubles. The Ministry of Agriculture has been led to take a part in this expedition in the expectation that its results will be of great service in developing the coast industries of the Amur and the Island of Saghalien, and also in the districts which have been acquired lately by the Russian Government. The Geographical Society also entertains great hopes of the successful results of this expedition, in view of the fact that the previous expeditions sent by it to investigate the Black, Azov, and Marmora seas were particularly successful. The expedition to the Far East will work in conjunction with the Society for Exploring the Amur Territory, and intends to establish at Vladivostock a zoological station for studying the marine fauna of the district.

*Science* states that the late Richard B. Westbrook, of Philadelphia, has made a bequest of 10,000 dollars, taking effect on the death of his widow, to the Wagner Institute of Science. The sum is to be used as an endowment of a special lectureship to "secure the full and fearless discussion by the most learned and distinguished men and women in our own and other countries of mooted or disputed questions in science, and especially the theories of evolution."

A YEAR ago Cornell University secured 30,000 acres of woodland in the Adirondack Mountains for the exclusive use of the University's forestry department. The land has been divided into a number of sections, and several seed beds have been laid out in which there has been planted over a million small trees of different varieties. The students of forestry will study the theory of the subject from October to April, and from then until Commencement they will study the practical side of forestry. Cornell University is, according to the *Scientific American*, the only college in the United States which has a forestry department.

THE *Scientific American* states that the men of science who have been investigating the Wyoming fossil beds are having remarkable success, and a large number of boxes containing fossil remains have been sent to the State University, and the work of restoration will soon be begun under the direction of Prof. Wilbur C. Knight.

DURING this summer a number of field parties in connection with the United States Fish Commission have been engaged, in various States, in ichthyological and other investigations. A camping party under the direction of Dr. Charles H. Gilbert has, says *Science*, systematically examined the coastal streams of Oregon, with reference to their fish fauna; the eastern tributaries of the Sacramento have been visited by Mr. C. Rutter; a comprehensive study of the biological and physical features of the Wabash basin has been begun under the direction of Prof. B. W. Evermann; a party in charge of Mr. W. P. Hay has explored the Monongahela basin in West Virginia; Dr. P. H.

Kirsch has been collecting and studying the fishes of the San Pedro River, Arizona; in connection with the biological survey of Lake Erie, Prof. J. Reighard and assistants have cruised along the northern and southern shores of the lake in a special steamer; Dr. H. M. Smith has visited Seneca Lake, N.Y., for the purpose of determining the character of its fish fauna; a study of the variations of the mackerel of the east coast has been conducted by Mr. M. C. Marsh, and in the interesting Sebago and Cobbosseecontee lake regions of Maine, Dr. W. C. Kendall has made some special investigations regarding salmon and other fishes.

THE return of the schooner *Julia E. Whalen*, after an absence of nearly a year, is announced in *Science*. The vessel was sent out by Stanford University on a scientific cruise among the Galapagos Islands, &c., and carried members of a scientific expedition under the direction of R. E. Snodgrass, entomologist, and E. Heller, zoologist. A large collection of specimens, including birds, mammals, invertebrates, and fish, was obtained. On board the vessel were eighteen live land tortoises taken from Duncan and Albemarle Islands, some of them weighing four hundred pounds; also 220 fur sealskins and 2300 skins of hair seals.

A REMARKABLE demonstration of the success of inoculation against the plague is to be found in the statement recently made to the Indian Imperial Research Laboratory by Dr. Chinoy, the medical officer of the Southern Mahratta Railway at Hubli. In Hubli itself 4961 persons were inoculated once, 7840 persons twice, and 1346 persons thrice (these having been twice inoculated last year), or a grand total of 14,147. In the district 1849 persons were inoculated once, and 1967 twice, or altogether in Hubli and the district a total of 17,963 persons. In the words of Dr. Chinoy: "There are about 1000 people living in the railway chawl, Hubli, which was seriously infected last year. *All of them are inoculated*, and I am glad to be able to state that *not a single case of plague* has occurred amongst them since plague broke out in the town, although they freely move about and mix with people in the town, where plague is increasing daily."

THE report of the Imperial Bacteriologist at Calcutta for 1898–99 states that a considerable quantity of mallein and tuberculin are being manufactured in the laboratory for veterinary use. The hope is expressed that arrangements may be made for dairy and other cattle to be tested with tuberculin, so as to ascertain the extent of tuberculosis amongst cattle in India. Attention has been given to the further investigation of "surra," and the report says it is more than ever probable that this disease is identical with the South African tsetse-fly.

THE Vienna correspondent of the *Times* reports some experiments in a new system of telegraphy made in Budapest and Berlin on Friday last. These are alleged to have given the extraordinary result of a transmission of no fewer than 220 words in ten seconds without prejudicing the clearness of the message. According to the reports from Budapest, the impression made upon the technical experts who had an opportunity of following the trial was favourable. A perforated roll of paper, similar to that at present in use, is employed for the despatch of the message, which is made visible and fixed photographically at the receiving station. Instead of the dashes and dots of the Morse alphabet there are rising and falling strokes starting from a horizontal line. The receiver consists of a telephone fitted with a small concave mirror, upon which are reflected, in the form of streaks of light, the impulses marked on the membrane. By an ingenious arrangement, recalling in some respects that of the cinematograph, the streaks of light reflected upon the mirror are reproduced upon a roll of sensitised paper, thus giving a narrow oblong picture, which in the present stage of the invention is developed and fixed like any ordinary photograph.

THE fumigation of trees for the destruction of insect pests has for some time been extensively used in California and other parts of the United States. The process will probably soon come into use in New South Wales, for Mr. W. J. Allen describes in the *Agricultural Gazette* of the Colony some very successful experiments in spraying and fumigating for red and other scales on orange trees. The tree to be treated is completely covered with a tent, such as is shown in the accompanying illustration, and is subjected for nearly an hour to the fumes of hydrocyanic acid, produced by the combination of sulphuric acid and potassium cyanide. The number of men generally employed in a fumigating gang is four or five, according to the size of the trees. One man introduces the chemicals, another looks out for the generator and measures the acid, and

Placing tent over tree to be fumigated.

two or three handle the tents. Such a gang can handle from thirty to forty medium-sized tents, and cover four to six acres of orchard in a night. Fumigation is to be preferred above spraying, because the trees are not in any way damaged by the fumes, except in the case of a few of the tender leaves, while the solution used in the sprays must to a certain extent close the pores of the tree and slightly weaken it.

ACCORDING to the *Engineer*, the signalling on the whole of the Pennsylvania Railroad system is now operated electrically. When a train passes a signal bridge it closes an electric circuit, which moves a signal semaphore to the "danger" position. When the train passes beyond the next bridge a circuit is opened, and the signal indicates that the block from which the train has just passed is clear. Finally, when the train passes beyond the third bridge, another signal arm on the same post drops, showing the driver of an approaching train that there is nothing on the next two blocks ahead.

THE connection between fleas and the permanency, or otherwise, of continents might not at first sight be very apparent, but, nevertheless, some important evidence on the latter point is afforded in a paper by the Hon. N. C. Rothschild published in *Novitates Zoologicae* for December last. In this contribution the author, who is making fleas his special study, describes a new species of those insects on the evidence of a single specimen from Argentina, which is believed to take up its abode on a rat. Now this Argentine flea, which is remarkable on account of the helmet-like shield covering the head, is provisionally assigned to a genus (Stephanocircus) hitherto represented by a single Australian species infesting the spotted dasyure (*Dasyurus maculatus*). And we presume it may be taken for granted that, whether or no they are rightly regarded as congeneric, the two species are evidently very closely allied. Now this being so, it is difficult to see how they reached their respective habitats except by means of a direct land connection between Australia and South America; and they accordingly serve to confirm the evidence afforded by the occurrence of the chelonian genus Miolania in both areas, to which attention has been recently drawn in these columns.

THE discovery of a new generic type of marine gastropod, represented by a species whose shell is over six inches in length, is such a rare event, that Mr. G. B. Sowerby's description of *Neptuneopsis gilchristi*, from the Cape seas, demands a brief notice. In general form the shell (which is described in the publications of the Cape Department of Agriculture for 1898) is so like some of the *Buccinidae*, such as *Neptunea* (*Chrysodomus*) that, were it not for its curiously swollen apex, it might be referred to the genus mentioned. On the other hand, the tricuspid tooth-ribbon, or radula, is of the characteristic volute type; and Mr. Sowerby consequently infers that the new genus should be placed in or near the *Volutidae*. If included therein, it will represent an interesting annectant, and therefore generalised type. The generic name selected scarcely seems to us a happy one.

THE close study of the smaller mammals of Europe on the lines followed by the American naturalists for those of their own country is gradually bringing to light the existence of numerous local races of species hitherto quite unsuspected. A remarkable instance of this is Mr. Barrett Hamilton's recognition of two new forms of mice from St. Kilda, which are described in the June number of the *Proc. Zool. Soc.* The first of these (*Mus hirtensis*) is nearly allied to the wood mouse (*M. sylvaticus*); while the second (*M. muralis*) is as closely related to the common house mouse. The former the author regards as indigenous to St. Kilda since the period when that island was connected with the mainland; while the latter he considers to have been derived from individuals of *M. musculus*, introduced by human agency not more than a few hundred years ago. Yet both differ from their mainland prototypes to the same degree; and thus indicate the different inherent variability of different species. The variation displayed by *M. muralis* is probably in the direction of the wild ancestor of *M. musculus*.

IN the *Indian Meteorological Memoirs*, vol. vi. part v., Mr. Eliot contributes a very important discussion of the air movement at Simla and in the Western Himalayas, deduced from anemometric observations recorded at Simla during four years ending August 1896. Some fifty years ago Sir Richard Strachey made a lengthened series of observations, chiefly in Kumaon, and in his description of the diurnal variation of the wind he considered the most important feature of the air movement in the Western Himalayas to be the up and down valley winds. Mr. Eliot's discussion entirely confirms this view. He states that the examination of the wind data from every point of view shows that the most important and unique feature of the air movement is the alternating currents between the hills and plains. He states that it is a permanent feature, independent of the change of seasons, and also of the air movement in the plains of Northern India, and is due to the changes of pressure vertically produced by the unequal expansion and contraction of the lower and middle strata of the atmosphere over the plains of Upper India and the Western Himalayan mountain zone.

THE *U.S. Monthly Weather Review* for June contains particulars of the increased usefulness of the Canadian Weather Service. For the year 1896 (the last published) the Report consists of two large quarto volumes, instead of one octavo volume published a year or two previously. During that year there were more than three hundred stations of observation of various classes. At the chief stations (eight in number), the telegraphic reporting stations, and a few of the special stations, the observers are paid, but the great bulk of observers are volunteers. There are thirty telegraphic stations, whose reports are received in Toronto before 9.30 a.m., and which, combined with fifty-four reports received by exchange from the United States, enable the director at Toronto, Prof. Stupart, to issue daily weather maps and forecasts similar to those published by other meteorological offices. The second volume is wholly taken up with details and results of the observations made at the eight chief stations. For each of these the Report gives for every hour and day the complete record of all the principal meteorological elements, in a form closely corresponding to that recommended for international meteorological publication of detailed observations. Prof. Cleveland Abbe's comment upon the work is that it is a noble contribution of data needed for the study of climatology in its relation to every matter that interests civilised humanity.

AN investigation of the emission and absorption of platinum-black and soot, and their dependency on the thickness of the layer employed, forms the subject of a paper by F. Kurlbaum in *Wiedemann's Annalen* (67). It would appear that both substances closely approach a black body in their behaviour towards waves of the length emitted by a black body at a temperature of 100°. For shorter waves the power of absorption increases. Both platinum-black and soot satisfy the Stefan-Boltzmann law when a sufficiently thick layer exists at high temperatures; and any deviations from this law are due to the radiating surface, or the bolometer being too thinly coated. Several further results of interest are found, and the author considers that for several reasons platinum-black is better than soot in all experiments.

IN the *Transactions* of the Institution of Mining Engineers, M. A. Rateau, Professor at the School of Mines, St. Etienne, describes experimental investigations on the theory of the Pitot tube and Woltmann mill, which are employed by engineers in gauging the rate of flow of air and water. Although the Pitot tube and mill and fan anemometers measure accurately the velocity of currents when these currents are uniform, they give, under opposite conditions which usually prevail, indications of the mean velocity which are always exaggerated, and are the more exaggerated the more marked the irregularity of the current itself. M. Rateau finds that the equation $v = a + bn + c/v$ which holds for low velocities in connection with such meters should, for velocities unrestricted in magnitude, be written in the form $bn = v - c/v - f(v)/v$, where $f(v)$ is a function of the resistance of the fluid with regard to which our knowledge is still somewhat deficient. In a note added later attention is drawn by the author to subsequent experiments by Mr. Epper, bearing on the same subject.

As there are insufficient data on the normal relations of voluntary movement to consciousness, Dr. R. S. Woodworth

has set himself to this study, and his results are published as a monograph—"The Accuracy of Voluntary Movement"—in *The Psychological Review* (vol. iii. 1899). The following are some of his conclusions: When the eyes are used, the accuracy of a movement diminishes as the speed increases; but it does not vary so much when the eyes are not used; the right hand is slightly more accurate than the left. When the interval between successive movements is kept constant and the speed of the motion alone varied, the accuracy diminishes rapidly as the speed increases, the accuracy also diminishes on keeping the speed constant and varying the interval alone; the accuracy of initial adjustment is favoured by a short interval, accuracy of current control by a low speed; fatigue increases the variability of a performance, but practice decreases it, variability means improvability. Finally, the author advocates a new mode of writing, as he finds that the side to side movement of the wrist and forearm possesses advantages in point of ease and of speed over the usual thumb-and-finger movement, or a movement of the whole arm from the shoulder.

Dr. Mario Baratta has contributed a preliminary sketch of his work on the Latian earthquakes to the *Rivista Marittima* for August. He shows that the more important shocks are connected with certain definite seismic centres, the positions of which he determines. An interesting comparison is made between the earthquakes of an extinct volcanic region, such as the Alban Hills, and those which precede, accompany and follow an eruption of an active volcano such as Etna. In both, the disturbed areas are as a rule extremely small, and yet near their centres the shocks may be strong enough to damage buildings. Also, in successive shocks, there are many changes in the positions of the epicentral areas.

M. A. de Gramont sends a reprint of an article describing a method he has devised for varying the scale and dispersion of a laboratory spectroscope (*Comptes rendus*, vol. cxxviii., p. 1564, June 1899). The scale is adapted in the usual way by placing it at the end of a collimator tube and arranging that the light from the scale shall be reflected from one face of the prism into the observing telescope; but instead of having only one lens in the scale tube, fixed at its principal focus from the scale, there are two lenses there, whose distances from each other and from the scale can be varied by known amounts. It will be at once apparent that the effect of this will be to alter the magnification of the scale as seen in the observing telescope, and in practice the scale is so altered that a certain number of divisions always correspond to the distances between the same two spectrum lines, whatever kind of prism or dispersive arrangement is being used. The variation in the dispersion is obtained in a well-known but little used manner, by rotating the prism about its refracting edge, and using positions more or less removed from that of minimum deviation, the dispersion being increased or decreased accordingly as the prism is turned towards the collimator or telescope from the mean position. A useful diagram is given bringing together the various effects on the dispersion by gradual displacements of the prism. The author is investigating more closely the variation of dispersion with the angle of incidence, and will communicate results later.

An observation of some interest in connection with recent discussions on heredity is recorded by M. Casimir de Candolle in a paper read before the *Société de physique et d'histoire naturelle de Genève*. He points out a constant difference between the normal and the adventitious buds of trees. The latter he regards as new individuals of the same species as the tree from which they spring, or as apogamic embryos, while the former are simply organs for prolonging the life of the individual. It is quite common for the first leaves of a woody plant to differ in form or structure from the later leaves. Examples are given in *Eucalyptus globulus*, the walnut, the horse-chestnut, and the hornbeam. In all these cases the first leaves from adventitious buds resemble, not those from normal buds, but the first leaves of the young plant.

A second edition of Dr. M. M. Richter's tables of carbon compounds is in course of publication by the firm of Leopold Voss, Hamburg and Leipzig (London: Williams and Norgate), under the revised title of "Lexikon der Kohlenstoff-Verbindungen." How tremendous has been the advance in the knowledge of carbon compounds since the original work appeared may be judged by the fact that the total number of compounds registered in the new edition is 67,000, as compared with 16,000 known in 1883. The work will be an index to Beilstein's handhook of organic chemistry, for all the compounds—about 57,000—contained in Beilstein are dealt with. Papers published up to the end of last year have been used in the preparation of the volume, and it is intended to publish annual supplements in order to keep the work up to date. The "Lexikon" will be completed in about thirty-five parts, twelve of which have been issued.

Messrs. Whittaker and Co. have published a second edition, thoroughly revised, of "An Introductory Course of Practical Magnetism and Electricity" by Mr. J. Reginald Ashworth. The book contains an admirable course of experimental work suitable for students in "Schools of Science" and other institutions where physics is taught by laboratory practice. A number of new illustrations have been added to assist students to understand descriptions of experiments.

Calendars, for the session 1899–1900, have reached us from the Merchant Venturers' Technical College, Bristol, and the Birkbeck Institution, London, in each of which all necessary information is to be found as to the various activities in connection with the two institutions. We notice that at the Merchant Venturers' College certain extensions and improvements have recently taken place; *e.g.* a new optical laboratory has been opened in connection with the Department of Applied Physics and Electrical Engineering, the amount of space available for the dynamo and testing-room has been doubled, and a battery, &c., have been added to the equipment. In addition to these, other changes have either taken place or are in progress.

Two articles of scientific interest are to be found in the current issue of the *Humanitarian*—one, by Mr. E. W. Brabrook, entitled "Anthropology, 1863–1899"; the other, by Dr. D. Somerville, on "The Rise of Bacteriology." Each gives in brief outline some idea as to what has been accomplished in the two branches of science. A reproduction of a striking photograph of Mr. Brabrook forms a frontispiece to the number.

We are asked to say that the lectures to young people, referred to in the last issue of Nature, p. 538, are to be delivered by Mr. Cecil Carus-Wilson during the months of October and November, and not as was stated.

The additions to the Zoological Society's Gardens during the past week include five Barbary Turtle Doves (*Turtur risorius*) from Africa, presented by Mrs. J. A. Moore; one Ruffed Lemur (*Lemur varius*) from Madagascar, two Westermann's Eclectus (*Eclectus westermanni*) from Moluccas, a Two-spotted Paradoxure (*Paradoxurus binotata*) from West Africa, a Rufous Tinamon (*Rhynchotus rufescens*) from Brazil, a Grey Ichneumon (*Herpestes griseus*) from India, four Blanding's Terrapins (*Emys blandingi*) from North America, deposited; a Black-necked Swan (*Cygnus nigricollis*) from Antarctic America, a Hoopoe (*Upupa epops*), two Sandpipers (*Tringoides hypoleucus*), European, two Lanceolated Jays (*Garrulus lanceolatus*) from the Himalayas, purchased.

## OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN OCTOBER:—

October 7. 10h. 18m. Minimum of Algol ($\beta$ Persei).
9. 14h. Saturn in conjunction with the moon (♄ 1° 27′ N.).
10. 7h. 7m. Minimum of Algol ($\beta$ Persei).
10. 7h. 3m. to 8h. 10m. Occultation of 4 Sagittarii (mag. 4·6) by the moon.
11. 5h. Mars in conjunction with Jupiter, ♂ 1° 11′ S.
14. Vesta (mag. 6·5) in opposition to the sun.
15. Venus. Illumination portion of disc 0·991; Mars, 0·981.
16. 6h. 3m. to 7h. 2m. Occultation of 16 Piscium (mag. 5·6) by the moon.
16. 11h. 53m. to 13h. Occultation of 19 Piscium (mag. 5·2) by the moon.
18–20. Epoch of the October Meteors (Radiant, 91°+15°).
21. 8h. 37m. to 9h. 35m. Occultation of $K^1$ Tauri (mag. 4·6) by the moon.
21. 8h. 38m. to 9h. 34m. Occultation of $K^2$ Tauri (mag. 5·5) by the moon.
26. 6h. Venus in conjunction with $\alpha$ Libræ. ♀ 0° 6′ N.
29. 13h. Venus in conjunction with Jupiter. ♀ 0° 33′ S.
30. 8h. 50m. Minimum of Algol ($\beta$ Persei).

COMET E. GIACOBINI.—A telegram has been received from the Centralstelle at Kiel announcing the detection of this comet at the Nice Observatory for the first time during the present apparition. The observation was as follows:—

1899. Sept. 29d. 8h. Nice Mean Time. $\begin{cases}\text{R.A. 16h. 26m. 32s.}\\ \text{Decl.} -5° \ 10'\end{cases}$

The daily motion in right ascension is + 2m. and in north polar distance − 10′, so that the comet is moving slowly in a north-easterly direction. The position at the time of discovery on September 29 was about 3° north of the 5th magnitude star, $v$ Ophiuchi. The comet is merely described as "faint." Previous appearances of this visitor took place in September 1896 and June 1898.

A later telegram from Kiel announces that the comet has been observed at the Konigsberg Observatory, the measured position being:—

1899. Oct. 1d. 8h. 0·5m. $\begin{cases}\text{R.A. 16h. 31m. 0·7s.}\\ \text{Decl.} \ -4° \ 39' \ 50''\end{cases}$

TWO NEW VARIABLE STARS.—Dr. T. D. Anderson, of Edinburgh, announces in *Astr. Nach.* (Bd. 150, No. 3594) his discovery of two new variables.

(1) *In Hercules.*—A star, not mentioned in the B.D., whose position is

$$\left.\begin{array}{l}\text{R.A.} = 17\text{h. } 53\text{m. } 27\text{s.}\\ \text{Decl.} = +19° \ 30'\end{array}\right\}(1855)$$

was found in August to have a variation amounting to about 0·9 of a magnitude. The star is about 2′ or 3′ *north-preceding* the 9·2 magnitude star B.D. + 19°·3489.

(2) *In Cygnus.*—A star, not mentioned in the B.D., whose position is

$$\left.\begin{array}{l}\text{R.A.} = 20\text{h. } 9\text{m. } 44\text{s.}\\ \text{Decl.} = +30° \ 37'\end{array}\right\}(1855)$$

is at present (September 21) rapidly diminishing in brightness. Comparisons with the neighbouring stars B.D. + 30°·3958, 3963, 3964 showed the variation in magnitude to be from 8·5 to 9·2.

THE MELBOURNE OBSERVATORY.—The thirty-third report of Mr. P. Barrachi, the Government Astronomer at the Melbourne Observatory, Victoria, has recently been distributed, showing the work undertaken and the progress made during the period July 1, 1898, to February 28, 1899. The observatory is reported in good order, the instruments well cared for and in good working condition.

With the 8-inch transit circle 1571 observations have been made in right ascension, for determinations of azimuth, clock corrections and catalogue stars; also 1017 observations in north polar distance have been made in connection with latitude determination, catalogue stars and special zodiac stars. The catalogue stars were intended chiefly to be used in the reduction of the plates for the astrophotographic catalogue. The zodiacal stars have been observed at the request of Dr. Gill, of the Cape Observatory, in connection with his heliometer observations of Neptune and the other major planets at opposition. All the reductions are well in hand.

*Astrophotographic Catalogue.*—The series of plates for the catalogue is now completed, and 387 plates for the Chart have been passed as satisfactory. Special series have been taken for the region round the South Pole, and seven plates have been exposed for the Oxford chart type. The measurement of the plates is being undertaken by six young ladies, using three micrometers. The probable error of a measured coordinate is now no more than 0″·1, which is within the prescribed limit. The progress of this part of the work is rather slow, but trials with Prof. Turner's scale, as adopted at Greenwich and Oxford, although permitting of much greater speed, showed the error to be as great as 0″·5, and therefore all the measurements are to be made with the filar micrometer. A new instrument, similar to that designed by Dr. Gill for the Cape, has been ordered from Messrs. Repsold and Söhne.

The various operations connected with the time service, meteorological observations, and inspection of outlying depôts have been carried out as in previous years.

*Terrestrial Magnetism.*—The photographic registration of the horizontal and vertical components and of the magnetic declination have been continued, absolute measurements and redeterminations of scale zeros being made *five* times. The measurement and reduction of the curves obtained since 1867, numbering some 30,000, have been commenced.

The photo-heliograph has been employed on sixteen days for solar pictures; 264 pairs of cloud photographs have been obtained with cameras placed at different points round the observatory buildings.

The great telescope and south equatorial have been used for comet and planetary observation, and for the use of visitors, 189 persons being admitted on Wednesday afternoons and 195 at night during the year.

## SIR ANDREW NOBLE ON THE BEST EDUCATION FOR ENGINEERS.[1]

WHEN your Dean first did me the honour to ask me to address you on the opening of your session, I had grave doubts as to whether I was a proper person to accept the invitation. On the one hand, I have had little or nothing to do with the education of others, and in some points my views, at all events so far as regards primary education, are at variance with much that is being done at the present day, but as, on the other hand, I have had exceptional opportunities of observing, both in this and other countries, certain points which seem to me to be of importance to those who propose to uphold the industrial supremacy of this country in the struggle which year by year other countries are rendering more and more severe, you therefore see me here to-day, and I shall consider myself amply rewarded if I can tempt but one of you to enter, for the sake of knowledge itself, the boundless fields which science day by day is opening up to you. I can promise that the pursuit will give you happiness. I hope it may give you wealth and distinction; but I remember the words of the Preacher, that riches are not always given to men of understanding, nor favour to men of skill, but that time and chance happen to us all.

Technical education is a phrase that has been so often misused, perhaps so often misunderstood, that many of those who, like myself, are engaged chiefly in trying to solve the practical problems of engineering are in the habit of hearing it either with impatience or of regarding it as a fad of lay theorists, or sometimes, I fear, as a cloak for educational shortcomings in other directions. And I am bound to confess, if their experience has been the same as mine, that there is some excuse for them. You can form but little idea of the number of persons of both sexes who have assured me that their sons had no taste for books, but had shown a marvellous talent for engineering. I need hardly tell you that the marvellous talent generally turns out to be an incapacity, possibly from defective education, for seriously applying the mind to any subject whatever.

But technical education, properly considered, is of the highest

[1] Inaugural Address of the Session 1899–1900 of the City and Guilds Central Technical College, given at the College, Exhibition Road, by Sir Andrew Noble, K.C.B., F.R.S., on Tuesday, October 3.

importance both to you and to England. It is only its abuse that we have to guard against.

Now one of the great abuses I take to be that technical education is often begun too early in life, that is, that it is substituted for a general education, and a boy attempts to put his knowledge to practical use before he has learnt how to learn.

Another abuse is the divorcing of practice from theory, and the danger of elevating practical application above scientific knowledge.

I shall try, therefore, to-day to say a few words, firstly, about the necessity of acquiring a sound general education before any special work is attacked, and, secondly, about the necessity of basing all practical work on theoretic knowledge.

I attribute the compliment which has been paid me in the invitation to speak at the opening of the present session to the fact of my having been connected, for many years past, with the management of probably the largest engineering firm in England. That position has afforded me exceptional opportunities for observing what educational antecedents are likely to produce the best results in the engineering field. I say "exceptional opportunities" advisedly, for we at present employ in our various works not far removed from 30,000 hands. Of these a large number are youths; often sons of workmen, but not unfrequently drawn from the class which I see represented before me.

I am continually asked what education I should recommend for a lad entering Elswick. I always say, "Send your son to as good a school as you can, keep him there as long as you can, do not curtail his time of schooling, do not stunt his early intellectual growth by narrowing it down to any special study as taught at elementary schools."

Science, mechanical drawing, and such like are no doubt very useful (as all knowledge is useful) in their way. These studies may prove an irresistible attraction to minds with a strong bent towards scientific subjects, but I would fancy most employers would rather that a lad came to us blankly ignorant of both, so long as he had had a good education, had been taught, and had ability to think, and to concentrate his attention on any subject brought to his notice.

Some of you may have heard, no doubt, the answer of the Duke of Wellington to a father who asked him what was the best education for his son, preparatory to his joining the army: "The best education you can give him."

It was a very pregnant utterance, terse and to the point, as nearly all the great Duke's were; and it remains as true for any other profession as for the army.

In nine cases out of ten, I should say, any knowledge acquired by a boy before he is sixteen can have but a slight intrinsic value. Up to that age, it is not *what* he learns that we have to look at, but *how* he learns; it is the habit of discipline, of mental application, of power in attacking a subject, that are so valuable; not, generally, any definite piece of knowledge he may have gained.

According to my experience, the most valuable knowledge that a man has at his disposal is that which he has taught himself. That a special technical education is not an absolute necessity is not difficult of proof My own chief, Lord Armstrong, commenced life as a solicitor; James Watt was an instrument maker, and was prevented from opening a shop in Glasgow because he had not served a full apprenticeship. George Stephenson was an assistant fireman to his father at Killingworth Colliery. Faraday was brought up as a bookbinder. I cite the cases of these great men simply to show how men without trained assistance have taught themselves, and what can be done by the dauntless energy, untiring industry and patient search after truth which were the great characteristics of all of them, and which enabled them to do such great things.

My own impression with regard to early education is that, as a sharpener of the young intellect, and as a mental discipline, it would be difficult to improve upon the curriculum which is now in force at our public schools, and which, in the main, has been in force for so many centuries.

I am not in accord with those who think that modern languages should supersede the classics as a means of education, and I should regret more than I do the attempts which have been made in this direction, did I think that these attempts were likely to be successful. Men of science will remember that practically the whole of our scientific nomenclature is borrowed from the Greek and Latin languages; and, personally, I have found my own knowledge of the classics—which represents, no doubt, that of a very ordinary schoolboy—stand by me, and enable me to enjoy, as I would not otherwise have done, that noble literature, which, as Lord Macaulay says, is the most splendid and perhaps the most durable of the many glories of England.

But, whatever may be the fate of the classics as a means, I must take up my parable against a course of education I have seen in several primary schools where an attempt is made to teach boys, often little better than children, rudimentary chemistry, rudimentary geology, also physiology and electricity.

Occasional popular lectures on these sciences may be of very great value to some boys in interesting them in these great subjects, and in leading them, at some later date, seriously to study them, but these sciences as taught in the schools I refer to can have but little value in encouraging habits of thought, of application, and of mental discipline; and to knowledge so acquired the words of Pope are peculiarly applicable:—

> "A little knowledge is a dangerous thing,
> Drink deep or taste not the Pierian spring,
> There shallow draughts intoxicate the brain,
> And drinking deeply sobers it again."

I am aware that many people say that the years a boy wastes on Greek and Latin might be better employed in learning German and French. It may be so, but it is not difficult to teach these most important languages colloquially at a very early age; and with regard to technical subjects, speaking from my own observation, I may say that I do not think I have known any man at twenty-eight or thirty who was the better for having abandoned his general education for technical subjects at too early an age.

Those men who, with fair abilities, have received a really good education, have been taught to use their minds, and who, by contact with other students, have acquired habits of application, amply make up for their late start by the power of mind and grip that they bring to their work. They are fresh and keen when others, who have been hammering away at semi-technical work from early boyhood, have become stale and are less vigorous, and that reflection moves me to deprecate strongly any attempt to teach seriously practical or electrical engineering in preparatory or elementary schools. As an excellent recreation, such studies are no doubt to be encouraged, but to make them a systematic part of education, to the exclusion of studies which have a more direct effect in developing the understanding, seems to me to be entirely wrong. I would go further and say that even in public schools, and their equivalents, for older boys, what are termed engineering shops are generally a failure, so far as any efficient knowledge to be gained in them is concerned. Except as a reasonable diversion for recreation hours, such "shops" have, I fear, but little value, and in nine cases out of ten the hours spent in them are subtracted from the time due to more valuable studies.

In my judgment, the age at which a boy should seriously begin any special studies, with a view to fit him technically for the profession he may have decided to follow, should not be earlier than seventeen or eighteen.

And in any discussion as to the age at which a boy should leave school, the great incidental advantages that he gains from a reasonable prolongation of his schooldays must never be lost sight of. A stricter discipline, a wiser supervision, a more authoritative yet sympathetic advice as to conduct, are more possible at school than can ever be the case in after life, and a more constant and generous association with his equals rubs off angularities and leads to amenity of disposition. It is seldom, indeed, that one cannot trace the difference between a lad who has had a full public school training and another who has been less fortunate. Speaking as an employer of labour, I should say that we find a pleasant speech and manner, tact in dealing with others, and some power of organisation of the utmost value; and it is precisely those qualities which a boy acquires, or ought to acquire, in his *later* years at a public school. Without such qualities even the highest scientific attainments will never make a captain of industry, and in selecting candidates for appointments the man-of-business distinctly prefers a youth who has had the benefit of some years at a good school.

So much for the necessity of grounding technical studies on the basis of a sound general education.

The next point I should like to urge is that any practical technical instruction and any practical knowledge acquired in the

workshop should be based upon sound theoretic knowledge. I am driven to enforce this question because (speaking again from my own observation) I find that in this country far too much weight is given to practical skill and what is called the "rule of thumb"; far too little to sound theoretic knowledge.

In the middle of this century English machinery was immeasurably superior to any other. To our remaining content with this state of things, and to our seriously neglecting technical instruction, I attribute the very much greater comparative progress that Germany, the United States and Switzerland have made in the last fifty years, and, if I am not very greatly mistaken, we shall have before many years, in the East, an important commercial rival in Japan, since that country is developing its manufacturing powers with an energy that is as remarkable as it is unexampled.

Turning to other departments of industry, no Englishman can observe without regret how certain branches have almost altogether abandoned this country, and been in a great measure left to those who have paid more attention to technical instruction.

Nearly every requirement of a drawing office can be better and more economically obtained from Germany. From what source do all our pure chemicals come, our filter papers and most of our glass apparatus? I admit that the workmanship of many articles made in England cannot be surpassed, but if we require any original or special piece of apparatus we are frequently compelled, as I have been, to go to Germany or France for their manufacture.

I do not desire to press my point too far, and admit that a portion of this transference of work, which I so much regret, may be due to cheaper labour. But the English mechanic is second to none, and if that false trade unionism, which endeavours to prevent the most intelligent and skilled from reaping the full benefit of their abilities, be abandoned, I do not despair of seeing this country regain much that it has now lost.

But it is to theoretic and technical knowledge that we must chiefly look. Consider, as an illustration, electricity in the service of man. Think of its innumerable applications, and of the number of hands dependent upon its industries. But for one man capable of designing or improving these powerful machines or delicate instruments, there are a thousand ready and able to carry out their designs. But it is the former who are the salt of the earth, and those who have the management of large concerns know well how to value them.

It was to meet the want that I am referring to that your Technical College was founded. Its objects are admirably stated in its programme, and your attention is drawn to the undoubted fact that no theoretic or technical instruction can supersede the necessity of obtaining practical experience in the workshop and factory. But, on the other hand, I believe that no genuine success in the higher walks of industry is probable without thorough theoretic or technical knowledge.

In my experience I do not think I have ever known a man rise to the top of the tree without it. I may, perhaps, be forgiven if I refer to one great engineering genius, Lord Armstrong, with whom it has been my privilege to be so long and so intimately connected. In whatever investigation he was engaged, he added to sound theoretic knowledge an intensity of application and an apparently intuitive perception of the results to be expected that I have rarely seen equalled.

Of him it may be truly said that "whatever his hand found to do, he did it with his might."

Sir William Harcourt, speaking a fortnight ago, attributed the immense commercial advance which has recently been made by Germany to the better teaching of languages, and to the German merchant being able to speak to the English buyer in a tongue which he can understand. I very much doubt if that has much to do with the matter, and I am sure that houses where business is done on a large scale very much prefer that all letters should be in the languages of the respective writers, and not in the doubtful English that is not unfrequently thrust upon us. There is no doubt that Germany is competing with us, as she has a right to do, successfully; and, so far as I am aware, with respect to her manufactures, perfectly honestly.

I say "honestly," because I do not believe in any attempt to enhance the value of one's own wares by depreciating those of other people; and I entirely differ from those who would attribute the success of our German competitors to their putting on the market inferior goods specially got up to imitate those of a superior class. It was some idea of this kind, no doubt, that led to the most ill-advised regulation that foreign-made goods should be stamped so as to show their origin. It doubtless does this, but its effect is, I believe, in the direction of an advertisement for foreign goods, and there is some danger that if our own manufacturers relax their efforts the "made in Germany," which was, I think, meant to be a reproach, should become, on the contrary, a hall-mark of excellence, as when the *Wilhelm der Grösse*, one of the finest steamships afloat, steamed into Southampton water with a facetious placard, "Made in Germany," hanging on her side.

In many articles, and especially with the apparatus of scientific research to which I have referred, this is already the case.

Manufacturing progress has in Germany gone hand in hand with material progress, and any one who has travelled much must be astounded with the extraordinary improvement which has been going on in recent years, not only in German railways, shipbuilding and steel-working, but also in the buildings, order and general amenities of life of the great German cities, such as Berlin, Frankfurt and Cologne. In the competition of manufacture we are pressed very hard from steel to watches, from marine engines to scientific instruments. In nothing, indeed, have German manufacturers made more progress than in the making of all exact instruments. In these departments Germany certainly excels us, so far as original and inventive improvement is concerned.

Now, all this improvement, I feel inclined to attribute, not, with Sir William Harcourt, to any linguistic superiority, but to the far greater opportunities of technical study which are afforded in Germany. If we are to hold our own, we older men must try to multiply these opportunities of study in our own country, and you younger men must do your part by seeking to avail yourselves to the uttermost of any such opportunities provided.

To you, gentlemen, who are about to commence the studies which will be useful to you in your future career, I venture to say a few words. Consider the marvellous progress that has been made in the physical and practical sciences during the century now rapidly drawing to a close. At the commencement of the century steam navigation and railways were unknown and unachieved. Our knowledge of the science of electricity was confined to a few isolated phenomena, and chemistry was in its infancy. Now the latter science has spread its branches until it seems likely it may bring into a common brotherhood the whole of the physical sciences. Consider, further, that knowledge and progress appear to be increasing in a geometric ratio; who then can predict what will be the progress made at the conclusion of the twentieth century, or even during the first half of it? In forwarding that progress I sincerely trust that many of those whom I now address may be prominent workers. We have never wanted in this country the men whom I would call the captains of the scientific army, but I think we are much inferior to Germany in the rank and file, in the number of men who are willing to follow particular lines of investigation, and who thus do invaluable service to science.

We older men, whose careers are approaching their termination, cannot but look with envy on the career which may be open to some of you. It was said of the telescope, which opened to our vision infinite space, that it was balanced by the microscope, which showed us the infinitely small; but small as are these objects, the kinetic theory of gases opens up to our appreciation, I had almost said to our view, molecules whose dimensions are inconceivably smaller. It would be vain to name to you the limiting dimensions of these molecules which have been revealed to us by the labours of Maxwell, Lord Kelvin, Clausius and others, but I have seen somewhere, possibly in the columns of NATURE, a statement which may be more intelligible. It was something like this:—That though the molecules of hydrogen gas are so small that it would take about 50 millions touching one another to make an inch, they are so numerous in a cubic inch of gas at 0° Centigrade and atmospheric pressure, that if the whole of them were formed into a row, they would go round the circumference of the earth more than a thousand times. The molecules also, as you probably know, are in violent motion. The highest velocity I have obtained with a projectile nearly reached 5000 f.s., but the average velocity of the hydrogen molecules at the temperature and pressure I have named is somewhat more. I once calculated that a few molecules, I forget in how many millions, might exceed 50,000 f.s.

We smile, and justly smile, at the seekers after what was

called perpetual motion. Modern science seems to show that it is equally vain to seek for anything that is perpetually and absolutely at rest.

I have alluded to the kinetic theory of gases because we know more of the constitution of that form of matter than we do of any other, but having regard to the progress of science to which I have referred, is it too much to hope that some of you will live to see a second Newton, who will give you a second Principia, which shall clear away the difficulties which surround the constitution of matter whether ponderable or imponderable ?

One word more, bring enthusiasm to your studies ; without it the best instruction (this you will have) and the best apparatus will do nothing for you. Make your work the first aim, and do not let athletics, or anything else, take precedence of it. Here, again, I cannot help thinking that the Germans get a little the better of us. With them work is absolutely in the forefront ; I am not at all sure that it is so with the average young Englishman of to-day. No one appreciates the value of athletics, when kept in their proper place, more keenly than I do. But against the substitution of athletics for the more serious objects of life, I should like to enter my strongest protest, and it will be a sorry day for England if such a change ever takes place.

Lastly, I would say to you, while giving the acquiring of knowledge that may assist your own business or profession the first place, not be too utilitarian, do not narrow the search for knowledge down to a search for utilitarian knowledge, for knowledge that you think will pay. I remember a strong protest of De Morgan's against the number of men who take their station in the business of life without ever having known real mental exertion ; he put it that knowledge which ought to open the mind was decided on solely by its fitness to manure the money tree.

Therefore, above all things, pursue knowledge. It is that pursuit which will stand by you to the end as at once the greatest and the most enduring of pleasures. Friends may die ; the most tender attachments must be severed ; advancing years will very soon debar you from any serious pursuit of athletics ; the acquisition of wealth will take away from you the pleasure of "making a position," which is probably the keenest, and surely the most legitimate, incentive of middle life ; but the pleasure of acquiring knowledge will console you to the last, so long as you have strength to open a book, or to hold a test-tube. Cry after knowledge ; seek for her as silver ; and search for her as for hidden treasure.

## *THE BRITISH ASSOCIATION.*

### SECTION H.

#### ANTHROPOLOGY.

OPENING ADDRESS BY C. H. READ, PRESIDENT OF THE SECTION.

THE difficulties that beset the President of this Section in preparing an address are chiefly such as arise from the great breadth of our subject. It is thought by some, on the one hand, to comprehend every phase of human activity, so that if a communication does not fall within the scope of any other of the Sections into which the British Association is divided, it must of necessity belong to that of anthropology. On the other hand, there are many men, wanting neither in intelligence nor education, who seem incapable of grasping its general extent, but, mistaking a part for the whole, are fully content with the conclusions that naturally result from such a parochial method of reasoning. The Oxford don who stated, a year or two ago, his belief that anthropology rested on a foundation of romance can only have arrived at this opinion by some such inadequate process, and the conclusion necessarily fails to carry conviction. The statement was, however, singularly ill-advised, for anthropology gives way to no other branch of science in its reliance upon facts for its existence and its conclusions. Had the reproach been that the facts were often of a dry and repellent character we might have pleaded extenuating circumstances, but I fear it must have been admitted that there was some justice in the complaint, though we could fairly point to instances where master minds have made even the dry bones of anthropology live, and that without trenching upon the domain of romance.

It is not, however, my purpose to-day to enter upon a general defence of anthropology as a branch of science. It has taken far too firm a hold upon the popular mind to need any such help. I intend rather to treat of one or two special subjects with which I am in daily relation, in order to see whether some practical means cannot be found to bring about a state of things more satisfactory than that at present existing.

The first of these branches is that of the prehistoric antiquities of our own country. It will not be denied that there can be no more legitimate subject of study than the remains of the inhabitants of our islands from the earliest appearance of man up to the time when written history comes to the aid of the archæologist. There is no civilised nation which has not devoted some part of its energies to such studies, and many of them under far less favourable circumstances than ours. The chiefest of our advantages is to be found in the small extent of the area to be explored—an area ridiculously small when compared with that of most of the continental nations, or with the resources at our command for its exploration. The natural attractions of our islands, moreover, have also had a great influence on our continental neighbours, so that their incursions have not been few, and no small number of them decided to remain in a country where the necessaries of life were obtainable under such agreeable conditions. The effect of these incursions, so far as our present subject is concerned, is that there is to be found in the British Islands a greater variety of prehistoric and later remains than is seen in most European countries, a fact which should add considerably to the interest of their exploration. At the same time also it must be borne in mind that it is by such researches alone that we can arrive at any true understanding of the conditions of life, the habits and religious beliefs, or the physical characters of the varied races who inhabited Britain in early times.

It may seem unnecessary to urge, in face of these facts, that all such memorials of the past should be, in the first place, preserved ; and, in the second, that any examination of them should be undertaken only by properly qualified persons. Unfortunately, however, it has never been more necessary than it is at the present time to insist upon both points, and the fact that these prehistoric remains are scattered impartially over the whole country, with the exception, perhaps, of the sites of ancient forests, makes it almost impossible to devise any special measures for their preservation. An additional difficulty is to be found in the fact that many ancient remains, such as the barrows of the early Bronze Age, are altogether unrecognised as such, and in the process of cultivation have been ploughed down almost to the level of the surrounding surface, until at last the plough scatters the bones and other relics unnoted over the field, and one more document is gone that might have served in the task of reconstructing the history of early man in Britain.

Such accidental and casual destruction is, however, probably unavoidable, and, being so, it is scarcely profitable to dwell upon it. We can, perhaps, with more advantage protest against wilful destruction, whether it be wanton mischief or misplaced archæological zeal. An enlightened public opinion is our only protection against the first of these, and will avail against the second also, but we are surely entitled to look for more active measures in preventing the destruction of archæological monuments in the name of archæology itself. It is a far more common occurrence than is generally realised for a tumulus to be opened by persons totally unqualified for the task either by experience or reading. An account may then be printed in the local journal or newspaper. When such accounts do appear it is often painfully obvious that an accidental and later burial has been mistaken for the principal interment, while the latter has been altogether overlooked, and no useful record has been kept of the relative positions of the various objects found. The loss that science has suffered by this indiscriminate and ill-judged exploration is difficult to estimate, for it should be borne in mind that an ancient burial, once explored, is destroyed for future searchers—no second examination can produce results of any value, though individual objects overlooked by chance may repay the energy of the later comers. So much varied knowledge is, in fact, required for the proper elucidation of the ordinary contents of a British barrow that it is almost impossible for any single person to perform the task unaided. A wide experience in physical anthropology must be combined with an acquaintance fully as wide with the ordinary conditions of such interments and the nature, material, and relative positions of the accompanying relics, all of which must be brought to bear, with discriminating judgment, on the facts laid bare by the digger's spade. Added to this, the greatest precaution is needed that nothing of value be overlooked. In

some soils, such as a stiff clay, it is almost impossible to guard against such a casualty, especially when the barrow is of large size and vast masses of earth have to be moved. The amount of profitable care that may be bestowed on scientific work of this character can nowhere be better seen, I am glad to say, than in our own country, in the handsome volumes produced by General Pitt-Rivers as a record of his investigations in the history of the early inhabitants of Dorsetshire. The memoirs contained in them are unsurpassed for scientific thoroughness, and they will probably long stand as the model of what archæological investigation should be. It is very seldom, however, that circumstances conspire so favourably towards a desired end as in the case of General Pitt-Rivers, where a scientific training is joined to the love of research, and finally ample means give full scope for its practice under entirely favourable conditions. While it is, perhaps, too much to expect that all explorations of this character should be carried through with the same minute attention to detail that characterises General Pitt-Rivers's diggings, yet his memoirs should be thoroughly studied before any work of the same kind is entered upon, and should be kept before the mind as the ideal to be attained. It is not too much to say that a diligent study of the works of the two foremost explorers of prehistoric remains in this country—Canon Greenwell and General Pitt-Rivers—will of itself suffice to qualify any intelligent antiquary to conduct the exploration of any like remains. At the same time, it must not be forgotten that exploration is one thing and a useful record of it is another, and here the explorer would do well to invite the co-operation of specialists if he would get the full value out of his work, and there is generally little difficulty in getting such help.

I have ventured to point out, in moderate terms, the dangers to which a large number of our prehistoric sites are liable, and to state under what conditions they should be investigated. It is not unreasonable to expect, if the danger is so obvious, that a remedy should be forthcoming to meet it. In most of the continental States it would be easy to institute a scheme of State control by which such sites would vest in the Government to just such an extent as would be necessary to prevent their being destroyed, and such a scheme might be cheerfully accepted and applied with success in any country but our own. Here, however, we are so accustomed to rely upon individual influence and exertion in matters of this kind, that an appeal to the Government is scarcely thought of; while, on the other hand, the rights of property are fortunately so safeguarded by our tradition and law that nothing but a futile Act of Parliament would have the least chance of passing. Moreover, experience teaches us that it is not to State control that we must look. The Ancient Monuments Bill, which was intended to protect a special class of monuments, and was framed with a full regard to the rights of owners, still stands in the Statute Book, but for years past it has had no effective value whatever. That being so, we must look to private organisations, and preferably to those already in existence, for some effectual moral influence and control, and, in my judgment, the appeal could best be made to the local scientific societies. Many of these are very active in their operations, and could well bear an addition to their labours; others, less active, might become more energetic if they had a definite programme. The plan I would propose is this:—Each society should record on the large scale Ordnance map every tumulus or earthwork within the county, and at the same time keep a register of the sites with numbers referring to the map, and in this register should be noted the names of the owner and tenant of the property, as well as any details which would be of use in exploring the tumuli. I am well aware that a survey of this kind has been begun by the Society of Antiquaries of London, and is still in progress; but this is of a far more comprehensive character, and is, moreover, primarily intended for publication. The more limited survey I now advocate would in no way interfere with it, but, on the contrary, would provide material for the other larger scheme. Once the local society is in possession of the necessary information just referred to, it would be the duty of its executive to exercise a beneficent control over any operations affecting the tumuli, and it may safely be said that such control could in no way be brought to bear so easily and effectively as through a local society.

Some of the arguments in favour of some such protection for our unconsidered ancient monuments have been already briefly stated, and, in conclusion, I would only urge this in their favour, that while the more beautiful monuments of later and historic times are but little likely to want defenders, the less attractive early remains are apt to disappear not so much from want of appreciation as from want of knowledge, and I would repeat that it is from them alone that we can reconstitute the life-story of those who lived in what we may, with truth, call our dark ages.

I will now ask you to turn your attention to another matter in which it seems to me that this country has opportunities of an unusually favourable kind. I refer to the collection of anthropological material from races which still remain in a fairly primitive state. It is somewhat trite to allude to the extent of our Empire and the vast number of races either subject to our rule or who look to us for guidance and protection. The number may be variously computed according to the bias, philological or physical, of the observer, but it will not be contested that our opportunities are without precedent in history, nor that they greatly exceed those of any existing nation. That being so, it may not be useless to see how far these opportunities are utilised. While it will not be denied that the Indian Government and the Governments of some of our Colonies have done excellent work in the direction of anthropological research and publication, and that exhaustive reports from our Colonial officials are frequently received and afterwards entombed in parliamentary papers, yet it is equally clear that work of this kind is not a part of our administrative system, but rather the protest of the intelligent official mind against the monotony of routine. The material, the opportunity, as well as the intelligence and will to use both, are already in existence, and all that is now wanted is that the last should be encouraged, and the work be done on a systematic plan, and, as far as may be, focussed on some centre where it may be available for present and future use. It was for this end that I ventured to bring before the British Association at the Liverpool meeting a scheme for the establishment of a central Bureau of Ethnology for Greater Britain. Frequent appeals had been made to me by officials of all kinds in distant parts of the Empire to tell them what kind of research work they could most usefully undertake, and it seemed a pity not to reduce so much energy and good will into a system. Hence the Bureau of Ethnology. The Council of the Association, on the recommendation of the Committee, invited the Trustees of the British Museum to undertake the working of the Bureau; this they have accepted, with the result that if the Treasury will grant the small yearly outlay it will be under my own supervision. If I had foreseen this ending I might have hesitated before starting a hare the chasing of which will be no sinecure.

It was considered necessary, before attempting to begin the work of the Bureau by communicating with commissioners and other officials in the various Colonies and Protectorates, to lay the matter before Lord Salisbury and to invite his approval of the scheme. The whole correspondence will appear in the Report of the present meeting, but I may be pardoned for quoting one paragraph of the circular letter from the Foreign Office to the several African Protectorates. It is as follows: "Lord Salisbury is of opinion that Her Majesty's officers should be encouraged to furnish any information desired by the Bureau, so far as their duties will allow of their doing so, and I am to request you to inform the officers under your administration accordingly." When it is remembered that this is strictly official phraseology, its tenor may be considered entirely satisfactory, and there can be little doubt that other departments of the Government will recognise the utility of the Bureau in the same liberal spirit. Thus we shall have within a short time an organisation which will systematically gather the records of the many races which are either disappearing before the advancing white man, or, what is equally fatal from the anthropological point of view, are rapidly adopting the white man's habits and forgetting their own.

The Bureau of Ethnology, however, will only perform a part of the task that has to be done. While there is no doubt of the value of knowledge as to the religious beliefs and customs of existing savages, it is surely of equal importance that anthropological and ethnological collections should be gathered together with the same energy. The spear of the savage is, in fact, far more likely to be replaced by the rifle than is his religion to give way to ours. Thus the spear will disappear long before the religion is forgotten. It may be said that we have collections of this kind in plenty, and it is true that in the British Museum, at Oxford, Cambridge, Liverpool, and Salisbury, there are indeed

excellent collections of ethnology, while at the College of Surgeons and the Natural History Museum there are illustrations of physical anthropology in great quantity. Whatever might be the result if all these were brought together, there can be no question that no one of them meets the requirements of the time. Here also there is a want of a system that shall at once be worthy of our Empire and so devised as to serve the ends of the student. Where, if not in England, should be found the completest collections of all the races of the Empire? It must be admitted, however, not only that we have no national collection of the kind, but that other nations are ahead of us in this matter. This could be readily understood if their sources of supply were at all comparable to ours. But this is, of course, very far from being the case. The sources are ours in great part, and if we stand inactive it is not unlikely that some will be exhausted when we do come to draw upon them. It is, perhaps, better to give here a case in point rather than to rely on general statements. In the summer of last year I arranged, with the approval of the Trustees, that Mr. Dalton, one of the officers of my department, should make a tour of inspection of the ethnographical museums of Germany, with a definite object in view, but at the same time that he should make a general survey of their system and resources as compared with our own. The report which he drew up on his return was printed and has recently been communicated to the newspapers; it is therefore not necessary to allude to it now, except to quote one instance confirming my statement that it is to a great extent from our Colonies that material is being drawn. Mr. Dalton says: "On a moderate estimate the Berlin collections are six or seven times as extensive as ours. To mention a single point, the British province of Assam is represented in Berlin by a whole room and in London by a single case." But even this, forcible though it is, does not adequately represent the vast difference between the material at the disposal of the two countries. For it is the habit of the collectors for the German museums to procure duplicates or triplicates of every object, for the purposes of exchange or study. It is thus not unlikely that the whole room referred to represents only a part of the Berlin collection from the British province of Assam. In making these observations, I should be sorry if it were thought that I wish to advocate a dog-in-the-manger policy, or that I consider it either desirable or politic to place any restriction upon scientific work in our Colonial possessions, even if such restrictions were possible. I would prefer to look at the matter from an entirely different point of view. If the German people, who are admittedly practical and business-like, think it worth while, with their limited Colonies, to spend so much time and money on the establishment of a royal museum of ethnography, how much more is it our duty to establish and maintain one, and on a scale that shall bear some relation to the magnitude of our Empire. The value of such museums is by no means confined to the scientific inquirer, but they may equally be made to serve the purpose of the trader and the public at large.

How can we best obtain such a museum? That is the question that we have to answer. It is scarcely profitable to expect that the Government will be stirred to emulation by the description of the size and resources of the Museum für Völkerkunde in Berlin. In the British Museum there is at the present time only the most limited accommodation even for the collections already housed there, and I am well aware that these form a very inadequate representation of the subject.

It may be thought that the solution of this difficulty is easy. It is well known that the Government has purchased the rest of the block of land on which the British Museum stands, and it may seem that such a liberal extension as this will form should be enough for, at any rate, a generation or two, and that a little additional building would meet immediate wants, and enable the collections, now so painfully crowded, to be set out in an instructive and interesting way. I admit that if the whole of the contemplated buildings were at this moment complete, and at least double as much space given to the ethnographical collections as they occupy at present, the difficulty would be much simplified. The collections could at any rate be then displayed far more worthily and usefully. Even this, however, would hardly meet the case, even if there were a certainty of the buildings being immediately begun. Such works as these, however, can only be executed in sections during the course of each financial year. Thus, even if a Chancellor of the Exchequer could be found to fall in entirely with the views of the Trustees, it would still be an appreciable number of years before the completion of the entire range of galleries that is contemplated. For this reason alone I do not look forward to obtaining the space that is even now urgently wanted for some time. Meanwhile the natural and legitimate increase of the collections at the rate of about 1 to 2 per cent. per annum still goes on, and the original difficulty of want of room would still face us, though in a lesser degree. This estimate of the rate of increase may seem a high one; but it should not be forgotten that the science is new, and that it is only within the last few years that such collections have been made on scientific lines, instead of being governed only by the attractive character or rarity of the object. The gaps that exist in such a series as that of the British Museum, made in great part on the old lines, are relatively more numerous than would be the case in museums more recently founded. Another reason, equally cogent, for allowing far more room than is required for the mere exhibition of the objects is that, in my judgment, ethnographical collections, to be of real value, need elucidation by means of models, maps and explanatory descriptions, to a far greater extent than do works of art, which to the trained eye speak eloquently for themselves. Such helps to understanding necessitate a considerable amount of space, though the outlay is fully justified by their obvious utility, and in any general scheme of rearrangement of the national collection they should be considered an essential feature.

There is yet another factor to be considered. It has been the fashion in this country to consider remains illustrating the physical characters of man to belong to natural history, while the productions of primitive and uncultured races generally find a place on the antiquarian side. Thus the skull of a Maori will be found at the natural history branch of the British Museum, while all the productions of the Maori are three miles distant in Bloomsbury. Such an arrangement can perhaps be defended on logical grounds, but its practical working leaves much to desire, and the arguments for a fusion of the two are undoubtedly strong. For instance, the student of one branch would be unlikely to study it alone without acquiring a knowledge of the other, while the explorers to whom we look for collections usually give their attention to both classes of anthropological material. Here again, in such a case, there would be a call for still more space at Bloomsbury.

If I may be permitted to add one more to the requirements of what should be an attainable ideal, I should like to say that courses of lectures on anthropology delivered in the same building that contains the collections would form a fitting crown to such a scheme for a really Imperial museum of anthropology as I have endeavoured to sketch. There is but one chair of anthropology in this country, and admirably as that is filled by Prof. Tylor, he would himself be the first to admit that there is ample room and ample material to justify the creation of a second professorship.

It will be admitted that if my premisses are well founded the conclusion must necessarily be that we cannot look to the British Museum to furnish us eventually with the needful area and other resources for the installation of a worthy museum of anthropology. The difficulties are far too great for the Trustees to overcome, unless by the aid of such an exhibition of popular enthusiasm as I fear our branch of science cannot at present command. Failing the British Museum, which may be called the natural home of such a collection, we must look elsewhere for the necessary conditions, and I think they are to be found, although it is possible that, however favourable these conditions may seem from our point of view, difficulties may already exist or arise later.

It is not the first time that a scheme has been thought out for the establishment of a museum or kindred institution which should represent our Colonies and India. In the year 1877 the Royal Colonial Institute made a vigorous effort in this direction, and, in combination with the various chambers of commerce throughout the country, advocated the building of an "Imperial Museum for the Colonies and India" on the Thames Embankment, with the then existing India Museum as a nucleus. The arguments then brought forward were in the main commercial, but they are, if anything, more forcible now than they were twenty years ago. The competition with foreign countries has become keener on the one hand, while the bonds between the Colonies and the parent country are notoriously closer and more firm than at any previous time. No moment could thus be more opportune than the present for the foundation of a really Imperial Institution to represent our vast Colonial Empire.

The last sentence has, perhaps, given an indication of my solution of the question. The Imperial Institute at South Kensington has now been in existence for some time, and has passed through various phases. But its most enthusiastic supporters will scarcely claim for it entire success in its mission. Whatever may be the underlying causes, it must be admitted that such popular support as it possesses is scarcely founded on the performance of its functions as an Imperial Institute. It would seem, therefore, that something more is wanted—a more definite *raison d'être*—than it has at present, and this I think it will find in being converted into such a museum of anthropology as I have indicated, but, of course, as a Government institution. I am by no means an advocate of the creation of new institutions, if the old ones can adequately do their work, nor do I think that anything but ill would result from a general partition of the contents of the British Museum. The separation of the natural history from the other collections was painful, though inevitable, and no such severe operation can be performed without loss in some direction. But the removal of the ethnographical and anthropological collections from the British Museum to the galleries of the Imperial Institute would possess so many manifest advantages that the disadvantages need scarcely be considered. The Government has already taken over a portion of the building for the benefit of the University of London. The remaining portion would provide ample accommodation for the anthropological museum, as well as for the commercial side, that might properly and usefully be continued; its proximity to the natural history branch of the British Museum would render control by the Trustees easy; the Indian collections, which formed so important a feature in the scheme of 1877, are at this moment under the same roof; and finally the University of London has but to found a chair of anthropology, and the whole of the necessary conditions of success are fulfilled.

I have but little doubt that, wherever it might be placed, the creation of a distinct department of anthropology would of itself tend to the enrichment of the collections. It must be remembered that it is only since 1883, when the Christy collection was removed to the British Museum, that the ethnographical collections there can claim any kind of completeness. Until then one small room contained the few important objects of this kind that had survived from the voyages of Cook, Wallis and the other early voyagers. The public did not expect to find ethnography in the British Museum, and it is, in fact, only within the last few years that it has been generally realised that a gallery of ethnography exists there. If it were placed in such a building as the Imperial Institute, it would still remain part of the British Museum, and be under the guardianship of its Trustees; but it would obviously command more attention and support from the public than can be expected while it remains an integral part of a large institution which has as many aims as it has departments.

I began this address by stating that it would have a practical application. I trust that to others it may seem that what I have ventured to suggest is not only possible of achievement, but would also be beneficial to the branch of science that we represent. I should like to add that, as far as possible, I have tried to state the case as it would appear to one who regarded the situation from an entirely independent standpoint, and wishing only to discover the most practical solution of what must be admitted to be a difficult question. My allegiance to the British Museum, however, may well have tinged my views, unnoticed by myself. There are many other subjects that might well have formed the subject of an address at the present time. On such occasions as these, however, it is, I think, advisable to select a subject with especial reference to the needs of the time, and I know of nothing that is at the present moment more urgent in this particular direction, and in my judgment it will tend greatly towards the true advancement of science, the object we all have at heart.

## SECTION I.

### PHYSIOLOGY.

### Opening Address by J. N. Langley, F.R.S., President of the Section.

One might suppose that physiology, dealing as it does for the most part with structures—such as nerves, and muscles, and glands—which every one has and has heard of, would be eminently a science the newer aspects of which every one could readily understand. And in this supposition one would be encouraged by the frequency of the references in English literature to some part of our inner mechanism. More than a century and a quarter ago we find: "If 'tis wrote against anything, 'tis wrote an' please your worships against the spleen, in order by a more frequent and more convulsive elevation and depression of the diaphragm, and the succussations of the intercostal and abdominal muscles in laughter, to drive the gall and other bitter juices from the gall-bladder, liver and sweetbread of his Majesty's subjects, with all the inimicitious passions which belong to them, down into their duodenums."

It must, however, be recognised that many subjects which are most interesting to the physiologist either involve so much special knowledge, or are so beset with technical terms, that it is difficult to make clear to others even their general drift.

I am not without uneasiness that my subject to-day may be found to fall within this category. I propose to consider some relations of the nerves which pass from the brain and spinal cord, and convey impulses to the other tissues of the body—the motor or efferent nerves; and in especial the relations of those efferent nerves which run to the tissues over which we have little or no voluntary control. It is as well to say at once that none of the general conclusions which I lay before you are encrusted with universal acceptance. One or two have been subjects of controversy for the last fifty years; others are too young to have met even with contradiction. I do not propose to give you an account of the various theories which have been put forward on the questions I touch upon, nor do I propose to point out how far the views I advocate are due to others. I am concerned only to state what seems to me to be the most probable view with regard to certain problems which have been emerging from obscurity in recent year.

*Limitations in the Control of the Nervous System over the Tissues of the Body.*—In view of the conspicuous manner in which nervous impulses affect every-day life, we are perhaps apt to over-estimate the character and range of the influence exercised directly by the nervous system.

From the early part of this century one way of regarding the body has been to consider it as made up of tissues grouped together in varying number and amount. Each tissue has its characteristic features under the microscope. We need not enter into the question as to which of the commonly recognised tissues of the body are to be regarded as forming a class by themselves and which are to be regarded as subdivisions of a class. The point I wish to lay stress on is that in any broad classification not more than two tissues are known to be supplied with approximate completeness with efferent nerve-fibres. The striated muscular tissue, which forms, amongst other parts of the body, the muscles of the limbs and trunk, receives in all regions nerve-fibres from the brain or spinal cord. And the unstriated muscular tissue, which forms, amongst other parts of the body, the contractile part of the alimentary canal and of the blood-vessels, is in nearly, and possibly in all, regions similarly supplied.

The glandular division of epithelial tissue in some parts responds promptly and strikingly to nervous impulses, but in some parts the response is feeble, and in others no nervous impulse has been shown to reach the tissue. The connective tissue which exists all over the body, and which in its varied forms of connective tissue proper—cartilage, bone, teeth, epithelioid cells—makes so considerable part of it, is in mammals, so far as we know, destitute of efferent nerve-fibres. The epidermic cells, which form a covering for the body, the ciliated cells, the reproductive cells, do not visibly respond to any nerve stimulus. And the myriads of blood corpuscles, which in different ways are in incessant action for the general welfare, are naturally out of range of nervous impulses. According to our present state of knowledge, large portions of the organism live their own lives uninfluenced, except indirectly, by the storms and stresses of the central nervous system. No nervous impulse can pass to them to make them contract or to make them secrete, or to quicken or slacken their inherent activity. The nervous system can only influence them through the medium of some other tissue by changing the quantity or quality of the surrounding fluid.

Regarding, then, the body from the point of view of the control exercised by the nervous system on the other constituents, we have first to recognise that this control is in considerable part indirect only, that the several tissues are in varying degree under direct control, and that different parts of

one tissue may be influenced by the nervous system to different extents.

*Limitation in the Control of the Nervous System over the different Activities of the Cell.*—Even when nervous impulses can strikingly affect the vital activity of a tissue, their action is limited. They cannot modify the activity in all the various ways in which it is modified by the inherent nature of the tissue and the character of the surrounding fluid. Thus the submaxillary gland which pours saliva into the mouth is in life ceaselessly taking in oxygen and giving out carbonic acid; it does this without pouring forth any secretion. So far as we know, no nervous impulse can hasten or retard this customary life of the gland by a direct action upon it without producing other changes. The nervous system can only do this indirectly by modifying the blood supply. The nervous impulse which reaches the gland cells causes them to secrete, to take up fluid on one side and to pour it out on the other, and it does not, and so far as we know it cannot, confine its influence to those changes ordinarily going on in the gland cells. The essential effect of a nerve impulse appears to be to modify the amount of energy set free as work; usually it causes work to be done, as in the contraction of a muscle, or in the secretion of fluid by a gland; sometimes it diminishes the work done, as in the cessation of a heart-beat, or the decrease of contraction of a blood-vessel. Other changes often go on side by side with this setting free of energy as work, but there is no unimpeachable instance in which these other changes take place by themselves as the result of nervous excitation. Physiologists have sought for long years in all parts of the body for nerves—calorific or frigorific nerves—which cause simply an increase or decrease of the heat set free by a tissue; and for nerves—trophic nerves—which cause simply chemical changes in the tissue associated with a setting free of heat or not. Probable as the existence of such nerves seems to be, the search for them cannot, I think, be said to have been successful.

*Somatic or Voluntary Tissues.*—When we look at the question of nervous control subjectively, and consider in ourselves what tissues are at our beck and call, we find that we have immediate and prompt governance over one tissue only, the one which, as we have already seen, is most universally supplied with efferent nerve-fibres—namely, the (fibrous) striated muscular tissue. The parts of the body composed of this muscular tissue we move, as we say, at will. We exercise a control over it that we cannot exercise over any other tissue. The tissue is supplied with a special system of nerves. In other vertebrates there is a tissue of similar microscopical characters, and having a similar system of nerves. And we can be certain that in all vertebrates the fibrous striated muscle and the nervous system belonging to it form a definite portion of the body which can be properly placed in a class apart from the other tissues of the body. The tissues in this class are spoken of as "somatic" tissues, or sometimes, in view of our own sensations, as "voluntary." "Voluntary" is not a word which physiologists care much to use in this context, because it readily gives rise to misconceptions. It will serve, however, if we bear in mind that the primary distinguishing characters of the system are microscopical, anatomical and developmental; that other tissues than "voluntary" can be put in action by the will, though in a different fashion; and that "voluntary" tissues are also put in action involuntarily. That is to say, the word will serve if we rob it of much of its ordinary meaning.

The somatic or voluntary nervous system has in its essential features long been known. We may leave it and pass on to a more obscure field.

*Autonomic or Involuntary Tissues.*—In putting on one side the voluntary system, you will notice that we have disposed of one only of the several tissues, differing microscopically from one another, which go to make up the various organs of the body. Of the rest some, as we have said, either do not receive nerve-fibres from the brain and spinal cord, or, if they do, practically nothing is known about them in our own class of vertebrates—the mammalia. These I shall say a word or two about later. For the present we must confine our attention to the tissues which are known to be supplied not too illiberally with nerve-fibres. These are unstriated muscle, and its allied cardiac muscle, and certain glands. Since the voluntary striated muscle has a nervous system of its own, it might be imagined that the unstriated tissue and the glandular tissue, differing as they do, would also have separate nervous systems. This, however, is not the case. The nervous supply of these two tissues have common features and belong to the same system. There is, unfortunately, no satisfactory term by which to designate it. On the whole the term "autonomic" seems to me best adapted for scientific use. But it is not of the first importance for our present purpose to insist upon a proper nomenclature, so that I think I shall not do much harm if I use the familiar "involuntary" for the unknown, or nearly unknown, "autonomic."

I need hardly point out how widespread are both the glandular and the unstriated muscular tissues. In man practically the whole surface of the skin is supplied with sweat-glands, lachrymal glands lie hid behind the eye, small glands are thick in the respiratory tract from the nose to the smaller bronchial tubes, and glands stretch along the whole of the digestive tract. Most of these can be set in action by nerve-fibres. There are a number of others in which such action has not been shown, so that they do not concern us at present. Unstriated muscle forming, as it does, part of the walls of the arteries and veins, penetrates to every part of the body. It forms a large part of the coats of the stomach and intestines; it is present in the spleen and in parts of the lymphatic vessels; it is present in the iris and in other parts of the eye; it occurs in greater or less amount in different animals in the deeper layers of the skin.

Consider some of the ways in which these tissues in the several organs or structures affect the working of the body. The heart contracts and supplies the driving force for the circulation of the blood; the arteries contract less or more, here or there, and regulate the amount of the blood to each region; the digestive tract secretes solvent and disintegrating fluids in the food, churns it into pulp, absorbs some and rejects the rest; the skin-glands pour out their tiny beads of perspiration, and so aid in regulating the temperature of the body; the iris commands the aperture of the pupil and determines the amount of light falling on the retina; the ciliary muscle, by its varying contraction, brings about the focussing necessary for distinct vision.

But the involuntary tissues do not confine themselves to actions of such flagrant utility as those just mentioned. The contraction of small bundles of unstriated muscles in the skin will cause the flesh to creep; other similar small muscles are attached to the hairs; 'tis these will make

> "Thy knotted and combinèd locks to part,
> And each particular hair to stand on end,
> Like quills upon the fretful porpentine."

The involuntary tissues, although not under the prompt and immediate control of the will, are under the control of the higher centres of the brain. They are particularly responsive to the emotions; and in so far as we can call up emotions, we can play upon them at will. The ease with which nervous impulses pass along given tracts depends, amongst other things, upon use. And so it appears that our great-grandfathers wept and our great-grandmothers fainted with an ease which we should require assiduous practice to attain.

Further, you may note that the contraction of involuntary muscle caused by an emotion may in its turn set up nervous impulses, which pass back to the brain and give rise to vague and curious feelings, feelings often lending themselves to effective literary expression:—

> "Where our heart does but relent, his melts; where our eye pities, his bowells *yearn*."

I must ask your forgiveness for mentioning so many well-known facts in the sketch which I have just given of the involuntary tissues. But I hope it will take from you all excuse for not understanding the rest of what I have to say.

*The arrangement of the involuntary nervous system* presents some peculiar characters. The most distinctive of these is that the nerves, after they leave the brain or spinal cord, do not run interruptedly to the periphery; they end in nerve-cells, and the nerve-cells send off the fibres which run to the periphery. The most direct proof of this lies in the fact that a certain amount of nicotine prevents the central nervous system from having any influence on the peripheral structures—*i.e.* the line is somewhere blocked; it can be shown, speaking generally, that there is no block on either side of the ganglia, so that it must be in them. The actual point of attack of the nicotine appears to be the connections made by the central nerve-fibres with the peripheral nerve-cells. Thus all nerve-impulses, which pass from the brain or spinal cord to unstriated muscle or glandular tissue, pass through an intermediate station on their way. In

this, as in some other respects, the arrangement of the involuntary nervous system is more complex than that of the voluntary nervous system; in the latter the motor nerve-fibres run direct to the tissue and have no nerve-cells on their course. The nerve-cells which form the intermediate stations for the involuntary nerve-fibres are grouped together into ganglia; and so we may call the nerve-fibres which run from the brain or spinal cord to the nerve-cells pre-ganglionic fibres, and the nerve-fibres which run from the ganglia to the peripheral tissues post-ganglionic nerve-fibres.

The involuntary nervous system is divided into at least two subdivisions. The most extensive of these is what is called the *sympathetic nervous system.* The pre-ganglionic fibres of the sympathetic arise from a limited portion of the spinal cord. They arise from that part of the spinal cord which is in the region of the chest and the small of the back—*i.e.* roughly from the part which lies between the origin of the voluntary nerves for the arms and the origin of the voluntary nerves for the legs. The fibres given off by the ganglia of this system—*i.e.* the post-ganglionic fibres—run to the involuntary tissue in all parts of the body.

*The Cranial and Sacral Systems.*—The second division of the involuntary nervous system consists of two parts: one part—the cranial—arises from the brain—*i.e.* above the origin of the sympathetic; the other—the sacral—arises from the end of the spinal cord—*i.e.* below the origin of the sympathetic.

Each supplies a limited and different part of the involuntary tissue of the body, but both together supply a portion only of it. Taking the distribution broadly, they supply the muscular coats of the alimentary canal and certain structures connected developmentally with the anterior and posterior portions of it. They are especially connected with these terminal portions; they send numerous nerve-fibres to them; whereas they send but few to the intervening portion, and none at all to its blood-vessels. Thus parts of the involuntary tissue of the body receive a double supply of nerve-fibres, whilst parts receive a single supply only. Amongst the latter are all the involuntary tissues of the skin, the blood-vessels of the limbs and trunk, and of most of the viscera.

The cranial and sacral divisions of the involuntary nervous system are considered by some observers to be simply portions of the sympathetic system separated from it by the development of the nerve-centres for the arms and for the legs. I may give one reason why I do not take this view. The middle portion of the spinal cord, which is the region that sends fibres to the sympathetic, always sends fibres to a given spot by more than one nerve, and usually by four or five. The fibres passing by the several spinal nerves never differ in the kind of effect they produce, but only in the degree of effect; the difference is in quantity and never in quality. If, then, regions above and below were mere separated parts of this sympathetic region, we should expect that when one of these regions and the sympathetic region sent nerves to the same spot, the effect produced by both sets of nerves would be the same in kind, though it might differ in extent. But this is often not the case. Thus certain blood-vessels may receive nerve-fibres from four spinal nerves in the sympathetic region and from three spinal nerves in the sacral region; all the former cause contraction of the blood-vessels, all the latter cause dilation. And thus it seems to me probable that in the evolution of mammals the sympathetic nerves have developed at one time, and the cranial and sacral involuntary nerves have developed at another time.

*Inhibition.*—A striking feature of the involuntary nervous system is its possession of nerve-fibres which, when excited, stop some action at the time going on. The most striking example is perhaps the cessation of the heart-beats brought about by excitation of the vagus nerve. Such nerve-fibres are called inhibitory nerve-fibres, and the stopping of the action is called inhibition.

So far as has been definitely proved inhibitory nerve-fibres only run to involuntary muscle and to nerve-cells, and to these, so far as has been certainly shown, only in particular cases. It is true that when fear or other emotion causes the tongue to cleave to the roof of the mouth, there is a cessation of the customary flow from certain glands, but this flow is itself the result of nervous impulses passing in ever rising and falling intensity from the central nerve-cells, and its cessation is due to inhibition of nerve-cells, and not to inhibition of glandular cells.

The inhibition of nerve-cells has only been proved to take place in the central nervous system. When a group of nerve-cells of the central nervous system is engaged in sending out nervous impulses, other nervous impulses reaching them by way of other nerve-cells may diminish or stop their activity. The theory which is commonly advocated now to explain this inhibition makes the activity of the nerve-cells depend upon their receiving stimuli from the minute endings of other nerve-cells, and the cessation of the activity to depend upon these minute endings, either withdrawing themselves out of range, or having something interposed between them and the nerve-cells, so that the impulses can no longer pass. This theory I do not wish to discuss to-day; it is sufficient to say that if it is true, the inhibition of nerve-cells is an entirely different process from that of the inhibition of involuntary muscle.

Turning to the inhibition of involuntary muscle, there is a source of confusion which we must first guard against. Nearly all the unstriated muscle in the body is kept in a state of greater or less tone, or contraction, by the central nervous system. A diminution or cessation of this contraction may then be caused by a diminution or cessation of the activity of the central nervous system. This cessation of contraction is, of course, not what we mean by an inhibition of the unstriated muscle. It is usually spoken of as an inhibition of the nervous centre. The inhibition we mean is that which is caused by stimulating the peripheral end of a nerve outside the spinal cord.

I have said that this inhibition can only be obtained in certain cases, and it is not easy to find anything in common with regard to these cases. But on the whole it appears that the more a tissue is able to work by itself, the more likely it is to be under the control of inhibitory fibres. The heart, stomach and the intestines work when no longer connected with the central nervous system, and these are especially liable to inhibition.

There has been a marked tendency amongst physiologists, in considering the question of inhibitory nerve-fibres, to take what may be called *the view of the equal endowment of the tissues.* Because some arteries have inhibitory nerve-fibres, therefore it is to be held as in the highest degree probable that all have. And many would go further and say that it is therefore in the highest degree probable that all unstriated muscle, and glands, and even the voluntary muscles, have such fibres. This view seems to me a mistaken one. There is hardly room for doubt that the motor fibres are supplied in most unequal measure to the unstriated muscle and glands of the body. There are veins in the body containing unstriated muscle, which show no visible contraction from any nerve stimulation. And there are a number of glands which no nerve—so far as we know—excites to secretion. Since in the course of the evolution of the organism, a universal development of motor fibres has not occurred, it is, I think, to be expected that the development of inhibitory fibres should be still less universal. For up to a certain point the results of inhibition can be obtained in most cases without inhibitory nerve-fibres, by a simple diminution in the impulses travelling down the motor fibres. The only, and the final, test is of course experiment. But not all experiments are decisive, and theory inevitably colours interpretation. This theory of the equal endowment of the tissues has, it seems to me, caused a number of quite inconclusive experiments to be accepted as offering satisfactory evidence for the existence of inhibitory nerve-fibres.

Passing from this question, we may consider briefly how far we can get on the way to understand what occurs during inhibition. The external characteristic feature of inhibition is that a certain state of activity ceases; a muscle contracting at short intervals ceases to contract, or a muscle in a steady state of contraction loses this state. The tissue in either case becomes flabby.

The activity of a tissue may obviously be due to its receiving some stimuli from the nervous system or to its own inherent qualities. In the former case, if the tissue were only active when receiving nervous impulses, we should naturally look to some interference with these impulses as being the cause of inhibition. The blood-vessels of the sub-maxillary gland appear to me to offer sufficiently clear evidence with regard to the inhibition of blood-vessels. The superior cervical ganglion is the local centre from which the nerve-fibres bringing about contraction run to the blood-vessels of the gland. When this ganglion has been removed and the nerve-fibres from it have degenerated, the vessels receive no nervous impulses causing them to contract. But stimulation of the inhibitory nerve will still cause dilation—*i.e.* inhibition of the blood-vessels. The

inhibition must then be due to a direct action on the tissue, and not to an interference with other nerve-impulses. The evidence with regard to the inhibition of the beat of the heart and of the tone or peristalsis of the alimentary canal is more complex, but there is good reason to believe that the contraction is in both cases due to their inherent qualities. And if this be granted, it follows that here also inhibition must be due to a direct action upon the tissue.

The contraction of a muscle is due to a chemical change in it. In this chemical change some energy is set free as work—shown by the contraction of the muscle—and some as heat. It is conceivable that the nervous stimulus which causes inhibition should cause all the energy set free by the chemical change to take the form of heat. In that case the inhibitory nerve would be a calorific nerve. The amount of chemical change is indicated by the amount of carbonic acid given off to the blood. No experiments have been made as to the amount of carbonic acid given off to the blood by an inhibited tissue, but it appears very unlikely that the amount is increased, and we may take this view of the action of an inhibitory nerve as improbable.

If the nervous impulse does not act in this way it must in some way stop the particular chemical change associated with contraction from taking place. It does not stop all chemical change, for blood passing through an inhibited tissue loses some of its oxygen. The simplest way for a nervous impulse to prevent a particular chemical change is to induce a different one. We have seen that the tissues which are inhibited have a great tendency to contract of themselves—that is, they form certain very unstable substances. In closely related tissues which are not inhibited this tendency exists but little or not at all. The

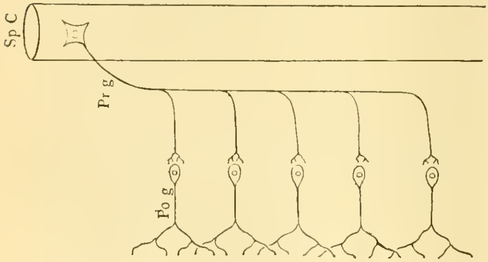

FIG. 1.

proximate cause of inhibition might then be that the nervous stimulus causes certain molecules of the tissue to form more stable combinations. This need not be associated with any general assimilation; it would simply make the muscle adopt for a time a mode of life more like that of other closely related muscle.

*Number of Relay Stations.*—I have already mentioned that the nerve-fibres which pass from the central nervous system to the involuntary tissues do not run to it direct, but end in groups of nerve-cells or ganglia from which fresh nerve-fibres are given off. Now, in most cases, there are anatomically several ganglia on a nerve in its course from the spinal cord to the periphery. For example, the nerve-fibres which cause the hairs of a cat's tail to stand on end, giving the tail the appearance of a bottle brush, leave the spinal cord in the lower part of the back, and enter a nerve-strand which is beaded with ganglia. They leave this strand near the root of the tail. Between the point where the nerve-fibres enter and the point where they leave the strand there are seven or eight ganglia. The fact offers us a problem of some difficulty. With how many of these ganglia are the nerve-fibres connected? Or, in other words, how many relay stations are there—eight or one, or some intermediate number? Further, do all kinds of involuntary nerve-fibres in all parts of the body have the same number of relay stations, or do some have one, some two, some three, and so on? It would take too long to discuss this question here. But the experimental evidence is, I think, fairly decisive in favour of the simple view that the nerve-impulse passes through one relay station only. There is, however, evidence that the nerve-fibres which pass from the spinal cord branch, so that we may take the element by reduplication of which the involuntary nervous system is built up to be diagrammatically as in Fig. 1.

*Reflexes.*—Another point of view is given by a comparison of the groups of nerve-cells of the peripheral ganglia with the groups of nerve-cells of the brain and spinal cord. The proper working of the body depends upon an agile response by the central nervous system to what is going on in the periphery. Now the peripheral ganglia are made up of nerve-cells and

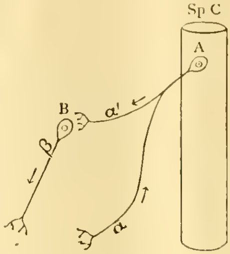

FIG. 2.

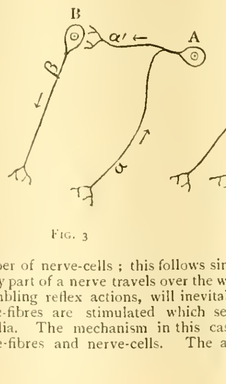
nerve-fibres which differ less in general characters from some of the cells of the central nervous system than these differ from one another. The nerve-cells of the spinal cord can receive impulses from many groups of nerve-cells both near and remote; they do not simply receive impulses from one quarter alone—say, the cortex of the cerebral hemispheres—but from many quarters, and notably direct from the periphery. Hence it has been supposed that the peripheral ganglia have similar wide connections, that they receive impulses direct from the periphery, that each is connected with other ganglia, and that impulses received from the periphery, or elsewhere, bring separate ganglia into coordinate action. And this view, which has been taken on general grounds, has been supported by microscopical observations.

The evidence against this view is of two kinds. In the first place, it can be shown that in a number of individual cases the nerve-cells of one ganglion have no connection with the nerve-cells of another ganglion, so that anything like a universal scheme of connection is out of the question. And, secondly, it can be shown that whenever an action occurs, which might be referred to such connection, it is an action which is bound to occur in consequence of some other known arrangement, and that therefore it is unnecessary to seek for a further cause.

The evidence of the first kind we need not enter into; the evidence of the second kind we may hastily touch on. If we accept the conclusion stated above, that the pre-ganglionic nerve-fibres branch, and the branches run to different nerve-cells, it follows that a stimulus applied to one branch will stimulate a



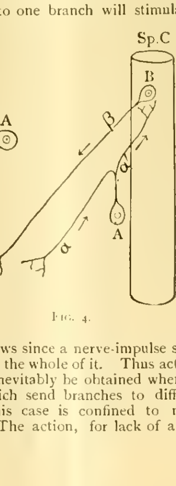


FIG. 3 FIG. 4.

number of nerve-cells; this follows since a nerve-impulse set up in any part of a nerve travels over the whole of it. Thus actions, resembling reflex actions, will inevitably be obtained whenever nerve-fibres are stimulated which send branches to different ganglia. The mechanism in this case is confined to motor nerve-fibres and nerve-cells. The action, for lack of a con-

venient term, was spoken of by Dr. Anderson and myself as a reflex action. It is perhaps better to call it a *pseudo-reflex action*.

Regarded from the customary point of view, a pseudo-reflex differs widely from a reflex action. The one is brought about by stimulating an efferent or motor fibre, and the other by stimulating an afferent or sensory fibre.

But suppose we compare them from another point of view. Fig. 2 is a diagrammatic representation of a pseudo-reflex. A nervous impulse passes up one branch $\alpha$ of a cell A, passes to another branch $\alpha'$, so excites a cell B and its nerve-fibre $\beta$.

Fig. 4 is a diagrammatic representation of a simple true reflex in the voluntary muscle. A nervous impulse passes up one branch $\alpha$ of a cell A, passes to another branch $\alpha'$, so excites a cell B and its nerve-fibre $\beta$.

You see the two can be described in exactly the same terms, and both are reducible to the diagram of Fig 3. It is true that the cells A and B are not similarly situated in the two cases; in the pseudo-reflex A is in the spinal cord, and B is outside it in a peripheral ganglion; whereas in the true reflex A is outside the spinal cord, in a spinal ganglion, and B is inside the cord. But then no one has even suggested that the position of a nerve-cell determines whether an action in which it takes part is a reflex or no. So that this point is irrelevant. And so it might be urged that the one action has as good a title to be called a reflex as the other. I do not, however, wish to insist too much on this comparison. I am inclined to say, after Touchstone, "An ill-favoured thing, sir, but mine own."

If, as some think is the case, the spinal ganglion cell receives the nerve-impulse conveyed by the peripheral nerve process, and modifies it before passing it on to the central process, this establishes a distinguishing character for the true reflex. It would be probably an axon plus dendron reflex, the pseudo-reflex being simply an axon reflex. The important known functional difference between the reflex and the pseudo-reflex is that in the former case the nerve-endings of the primarily affected nerve-fibre are specially differentiated for receiving nerve-impulses, and in the latter case these endings are specially differentiated for imparting nerve-impulses. And, on the whole, it is probable that the pseudo-reflex is not a normal part of the working of the body, but comes into play only as it were by accident. I do not, however, regard this as quite certain.

The pseudo-reflex I have spoken of is caused by the excitation of nerve-fibres before they reach the ganglia—*i.e.* of pre-ganglionic fibres. But the fibres which are given off by the ganglia also branch, so that it appears inevitable that we should have in certain circumstances an action related to a reflex caused by a stimulation set up in one of these branches spreading to the rest—*i.e.* a spreading out of impulses in post-ganglionic fibres similar to that which occurs in pre-ganglionic fibres. Turning to the diagram, Fig. 1, a nervous impulse set up in one branch—possibly by a contraction of muscle-cells to which it runs—would spread to other branches and cause contraction of the muscle-cells in connection with them. You will notice that this spreading out of impulses does not necessarily involve the stimulation of any nerve-cell; it might perhaps be distinguished as *irradiation*. It would, probably, be very local in action, unless there were overlapping of the districts supplied by the several nerve-cells, in which case a not inconsiderable spreading out of a local contraction might take place, giving rise to a peristaltic wave.

It must be pointed out that it has been assumed that in the sympathetic nervous system an impulse cannot pass from a motor fibre through the nerve-cell from which the fibre arises and affect any other nerve-fibre or nerve-cell. There is good ground for this assumption, but the experimental evidence might certainly be more complete.

To return to our main line of argument, we have good evidence that nervous impulses set up in one spot may affect regions more or less remote by a mechanism which does not involve the presence in the sympathetic system of special sensory nerve-cells with peripheral sensory nerve-endings. And so far as investigation has gone at present, I think that all the apparent reflex actions can be explained without reference to such sensory apparatus. And so I take the analogy of the peripheral ganglia with the central nervous system to be misleading, and consider that all the nerve-cells of which we have been speaking are motor nerve-cells, and that they all conform to the simple plan shown in Fig. 1. Thus the whole consists of a duplication of one type; a cell in the spinal cord which branches, each branch ending in a single cell; each of these cells sends off a nerve-fibre which branches, the branches ending in a group of involuntary muscle or gland cells.

That I regard as the real working mechanism, but there are two reservations to make. All the tissues of the body may be looked upon as engaged in a lifelong process of carrying out experiments, and I am prepared to believe that there are in the body what may be spoken of as the residues of these natural physiological experiments, either the beginnings of experiments which have not succeeded, or the melancholy ends of those which once partially successful have failed later. Such possibly may be the nerve-cells which have been described in sympathetic ganglia as sending their nerve-fibres to other nerve-cells.

Secondly, in this account I have not included the nerve-cells which exist in the wall of the alimentary canal, and the cells of Auerbach's and Meissner's plexuses. These "enteric" nerve-cells belong, I hold, to a system different from that of the other peripheral nerve-cells. With regard to their connections I do not think anything can be said with certainty.

*Regeneration. Specific Nerve Energy.*—One other problem presented by this involuntary system we may say a few words about. You know that when a nerve in the hand or arm is cut the nerve will in proper conditions grow again; and the lost feeling and the lost power over the muscles will return. The recovery is brought about by the part of the nerve which is attached to the spinal cord growing along its old track and spreading out as before in the muscle, skin and other tissue. At any rate, that is the method for which there is most evidence. You may know also that when the nerve-fibres in the spinal cord are similarly injured, they do not recover function. Regeneration in the latter case implies that the nerve-fibres have to form fresh endings in connection with nerve-cells. If this were more difficult than the formation of nerve-endings in muscle and other non-nervous tissues, the difference which exists as regards recovery of function between the nerve-fibres of the limb and nerve-fibres of the spinal cord would be readily explainable. But recent experiments show that the nerve-fibres which run from the spinal cord to the peripheral ganglia—*i.e.* pre-ganglionic fibres—re-form with ease their connection with nerve-cells, so that we may probably seek in mechanical conditions for the reason of the absence of regeneration of the fibres in the spinal cord. Possibly some way may be found of improving the mechanical conditions, and so obtaining regeneration. That question, however, we need not enter into.

The regeneration of the pre-ganglionic nerves presents some very remarkable features. The nerve-fibres which end in a sympathetic ganglion are rarely, if ever, all of one kind—that is to say, they do not all produce the same effects. Thus, of those which run to the ganglion in the upper part of the neck, some cause the eyelids to move apart, some cause the pupil to dilate, some cause the face to become pale, some cause the glands of the mouth or skin to secrete, and others have other effects. These different kinds of nerve-fibres run, in large part at any rate, to different nerve-cells in the ganglion. There are in the ganglion several thousands of nerve-cells closely packed together. And it would seem hopeless for each kind of nerve-fibre as it grows again into the ganglion during regeneration to find its proper kind of nerve-cell. Nevertheless, nearly all of them succeed in doing this. The nerve-fibres which normally cause separation of the eyelids, or dilatation of the pupil, or pallor of the face, or secretion from the glands, produce the same effects after several inches of their peripheral ends have formed anew.

The fact offers at first sight a striking proof of a specific difference between the different classes of nerve-fibres and different classes of nerve-cells. Through the matted mass formed by the delicate interlacing arms of the nerve-cells, the ingrowing fibres pursue their tortuous course, passing between and about hundreds of near relations until they find their immediate stock, whom they clasp with a spray of greeting tendrils and so come to rest.

Absolute laws seem unfitted for a workaday world. For closer observation shows that the fibres have not always this marked preference for their own stock. The nerve-fibres of the cervical sympathetic, the nerve I have spoken of above, do not often go astray, at any rate so far as is known. But they do sometimes; thus it may happen that some nerve-fibres which

ought to find their home with nerve-cells governing the blood-vessels, take up with nerve-cells governing the dilator structures of the pupil.

And if we turn to other nerves, greater aberrations are found. We have seen that the nerves running from the central nervous system to involuntary structures may be divided into two sets: the sympathetic nerves on the one hand, and the cranial and sacral nerves on the other. An important cranial nerve is the vagus; it causes, when in action, cessation of the heart-beat, contraction of the œsophagus, contraction or inhibition of the stomach, and various other effects. It does not send nerve-fibres to any of those structures of the head which we have seen the sympathetic ganglion at the top of the neck—the superior cervical ganglion—so liberally supplies. And yet the vagus nerve, if it has a proper opportunity of growing into the superior cervical ganglion, will do so, and there establish connections with the nerve-cells. Thus the nerve which properly exercises control over certain viscera in the thorax and abdomen is capable of exercising control over structures in the head, such as the iris, the blood-vessels and the glands. The details of the process, with which I will not trouble you, do not afford any clear evidence that the nerve-fibres of the vagus pick and choose amongst the nerve-cells of the superior cervical ganglion; the fibres appear rather to form their terminal branches around any kind of nerve-cell, so that, in fact, the action which the nerve-fibre will in future bring about depends, not on any intrinsic character of its own, but upon the nature of the action carried on by the nerve-cell. The nerve-cell may cause secretion from a gland, or contraction of a blood-vessel, or dilation of the pupil, or movement of hairs; whichever action it causes, the nerve-fibre which joins it from the vagus nerve can cause for the future, and it can cause no other. In this case, then, we arrive at results which are hopelessly at variance with the view that the nerve-fibres and nerve-cells of the involuntary nervous system are divided into classes which are fundamentally different. In other words, that theory which is spoken of as the theory of specific nerve-energy does not apply here.

But if this is so, how are we to account for the selective power shown by the sympathetic nerve-fibres which I have mentioned earlier? That the different classes of nerve-fibres and nerve-cells with which we are dealing have not those deep and inherent differences which are required by the theory of specific nerve-energy is, it seems to me, certain. Nevertheless, there may be some differences of a comparatively superficial nature which suffice to explain the selective activity observed. We may suppose that a re-growing nerve-fibre will in favourable circumstances join a nerve-cell the function of which is the same as that of its original cell, but that if there are hindrances in the way of this return to normal action, and if the conditions are favourable for joining a nerve-cell acting on some other tissue, why then it will join this. It is as if it had a preference, but did not care overmuch. We might perhaps express the facts by saying that there are different varieties of pre-ganglionic fibres, but no species.

We have been speaking so far of the nerve-fibres which run from the brain and spinal cord to the peripheral nerve-cells. The nerve-fibres which run from the peripheral nerve-cells have also, there is reason to believe, a large measure of indifference as to the kind of work they perform. The limits of this indifference have yet to be investigated.

I have said earlier that in mammalia nerve-fibres are not known to run to connective-tissue cells or to epidermic cells. But in some lower vertebrates certain connective-tissue cells are under the control of the central nervous system. Thus in the frog the pigmented connective-tissue cells, which play a large part in determining the colour of the skin, can be made to contract or to rearrange their pigment granules—and so change the colour of the skin—by excitation of certain nerves. In all probability, the motor nerve-fibres to the pigment-cells belong to the same class as the nerve-fibres which run to the arteries and to the glands—*i.e.* they belong to the autonomic system. We have seen that unstriated muscle-cells and gland-cells in different parts of the body are by no means equally supplied with motor nerve-fibres, and it may be that in mammals there are certain connective-tissue cells which receive motor nerve-fibres. Further, if it is true, as it well may be, that nerve-fibres which run to a gland are capable in favourable conditions of making connections with a blood-vessel, it is not beyond hope that either kind of nerve-fibre may experimentally, by offering it favourable conditions, be induced to join connective-tissue cells.

The factors which determine whether a particular tissue or part of a tissue is eventually supplied with nerve-endings, and the degree of development of these, are the factors which determine evolution in general. In the individual, it is exercise of function which leads to the development of particular parts; in the race, it is the utility of this development which leads to their preservation. And so it is conceivable that in some lower vertebrate at some time, the autonomic nervous system may have developed especially in connection with those tissues which appear in ourselves to be wholly unprovided with motor nerve-fibres.

I am tempted, before ending, to make a slight digression. Those who have occasion to enter into the depths of what is oddly, if generously, called the literature of a scientific subject, alone know the difficulty of emerging with an unsoured disposition. The multitudinous facts presented by each corner of nature form in large part the scientific man's burden to-day, and restrict him more and more, willy-nilly, to a narrower and narrower specialism. But that is not the whole of his burden. Much that he is forced to read consists of records of defective experiments, confused statement of results, wearisome description of detail, and unnecessarily protracted discussion of unnecessary hypotheses. The publication of such matter is a serious injury to the man of science; it absorbs the scanty funds of his libraries, and steals away his poor hours of leisure.

Here I bring my remarks to a close. I have endeavoured to give as clearly as possible what seem to me to be the conclusions which logically follow from certain data, but I would not have you believe that I regard them as representing more than the immediate point of view. As the wise man said: "Hardly do we guess aright at things that are upon earth, and with labour do we find the things that are before us."

## *AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.*

THE presidential addresses delivered before the Sections of Zoology and Botany of the American Association, by Profs. S. H. Gage and C. R. Barnes, respectively, are printed in *Science* of September 8. The subjects were "The Importance and the Promise in the Study of Domestic Animals" and "The Progress and Problems of Plant Physiology" and the subjoined extracts show some of the points dealt with. Abstracts of several other sectional addresses have already appeared in NATURE, p. 515.

Prof. Gage described a few ways in which the study of domestic animals has thrown light on the problems confronting mankind in his social ideals, in preventive medicine, in physiology and hygiene, in embryology and comparative anatomy and in the doctrine of the evolution of organic forms. He showed that, with the higher forms at least, that is the forms most closely related to man, and with whose destiny his own economic, hygienic and social relations are most closely interwoven, the domestic animals have in the past and promise in the future to serve the best purpose because of the abundance of the material in quite widely separated groups of animals which long have been and still are under greatly differing conditions and surroundings; and, finally, because this material is plentiful and under control, and thus may be studied throughout the entire life cycle.

There has been and still is too great a tendency in biology to study forms remote and inaccessible. This is, perhaps, partly due to the fascination of the unknown and the distant, and the natural depreciation of what is at hand. But study of these supposedly generalised types has proved more or less disappointing. No forms now living are truly primitive and generalised throughout. They may be in parts, but in parts only. The stress of countless ages has compelled them to adjust themselves to their changing environment, to specialise in some directions so far that the clue through them to the truly primitive type is very much tangled or often wholly lost. Indeed, every group is in some features primitive.

As any complete study requires much material at all stages the higher forms must be of the domesticated groups, or wild

forms must be practically domesticated for the time being to supply the material.

It may be objected, also, that in the investigation of domesticated forms sordid interests will play too prominent a part. No doubt to the true scientific man the study of zoology for its own sake, that is, for an insight into the fundamental laws of life, is a sufficient incentive and reward. Judging from the past, the study of the domestic animals in any other way than in a scientific spirit and by the scientific method will prove barren; but studied in that spirit and by that method the result has always justified the effort, and has thrown as much, if not more, light upon biological problems than an equally exact study of a wild form.

Therefore, while purely practical ends can never supply the inspiration to true scientific work, still surely no scientific man could feel anything but happiness that his work had in some ways added to the sum of human well-being. Perhaps no one has expressed so well the sympathy of a scientific man with his fellow-men as Pasteur in the preface to his work on the silkworm diseases: "Although I devoted nearly five consecutive years to the laborious experimental researches which have affected my health, I am glad that I undertook them. . . . The results which I have obtained are perhaps less brilliant than those which I might have anticipated from researches pursued in the field of pure science, but I have the satisfaction of having served my country in endeavouring, to the best of my ability, to discover a remedy for great misery. It is to the honour of a scientific man that he values discoveries which at their birth can only obtain the esteem of his equals, far above those which at once conquer the favour of the crowd by the immediate utility of their application; but in the presence of misfortune it is equally an honour to sacrifice everything in the endeavour to relieve it. Perhaps, also, I may have given young investigators the salutary example of lengthy labours bestowed upon a difficult and ungrateful subject."

In conclusion Prof. Gage summarised his address by saying: However necessary and desirable it may have been in the past that the main energy of zoologists should be employed in the description of new species and in the making of fragmentary observations upon the habits, structure and embryology of a multitude of forms, I firmly believe that necessity or even desirability has long since passed away, and that for the advancement of zoological science the work of surpassing importance confronting us is the thorough investigation of a few forms from the ovum to youth, maturity and old age. And I also firmly believe that, whenever available, the greatest good to science, and thus to mankind, will result from a selection of domesticated forms for these thorough investigations.

In the Section of Botany, Prof. Barnes discussed the chief features of plant physiology in which notable progress has been making during the last decade. The great advances in plant chemics and physics; the progress in the investigation of causes of plant form: the widening ideas of the property of irritability; the investigation of the social relations of plants, and the minute study of cell action in spite of their diversity, have one great end in view. This is nothing less than the solution of the great problem—the fundamental problem—of plant physiology as of animal physiology, namely the constitution of living matter. Entrenched within the apparently impregnable fortress of molecular structure this secret lies hid. The attacks upon it from the direction of physical chemistry and physiological morphology, of irritability, of ecology and of cytology are the concentrating attacks of various divisions of an army upon a citadel some of whose outer defences have already been captured. The innumerable observations are devised along parallel lines of approach, and each division of the army is creeping closer and closer to the inner defences, which yet resist all attacks and hide the long-sought truth.

One outer circle of defences yet remains untaken, and until that falls it would seem that there is little hope of capturing the inner citadel. More must be known of the constitution of dead substances chemically related to the living ones. When the students of chemistry can put the physiologists into possession of the facts regarding dead proteids, the attacks will be renewed more directly, with greater vigour and greater hope of success.

It is not possible to prove to-day that life and death are only a difference in the chemical and physical behaviour of certain compounds. It is safe to say that the future is likely to justify such an assertion.

## UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Eleven county and borough councils have arranged with the Board of Agricultural Studies to make grants for the maintenance of the new department of Agriculture established under the direction of Prof. Somerville. The first list of lectures issued by the Board includes some seventeen courses.

IN the valedictory address delivered by Dr. Hill on vacating the office of Vice-Chancellor, reference was made to the fact that before the close of the academic year the contributions to the Benefaction Fund amounted to upwards of 50,000*l.*; also that a commencement has been made with the new Geological Museum. The Museum will cost about 44,000*l.*, of which sum the fund raised as a memorial to Prof. Sedgwick will supply 27,000*l.*

---

A TECHNICAL and mining college is to be established at Wigan at an estimated cost of 40,000*l.*

THE Rev. J. F. Cross has been appointed professor of mathematics at St. John's University, Winnipeg.

PROF. A. MCADIE has been appointed honorary lecturer on meteorology in connection with the Berkeley Astronomical Department of the University of California.

MR. THEODORE MORISON has been appointed principal of the Aligarh Mahomedan College. The new principal, who is at present in this country, has been authorised to select two new professors to take out with him.

PROF. WAGSTAFF will lecture on geometry at Gresham College from October 10 to 13, and the Rev. E. Ledger's course of lectures on astronomy at the same institution will take place from November 14 to 17.

THE degree of Doctor of Pharmacy has just been conferred by the University of Paris for the first time. The recipient is M. Lacourt, whose graduation thesis was entitled "Historical, Chemical and Bacteriological Study of the Versailles Water."

THE fifteen universities of France together have a total of 27,080 students, of whom 12,059 belong to Paris. The total expenditure is 13,859,500 francs, so that the average cost of the education of each student is 511 francs (a trifle over 20*l.*). To meet this expense the universities have revenues amounting collectively to 2,093,700 francs; legacies, donations, &c., amount to 1,511,600 francs; therefore a deficit of 10,524,200 francs (equivalent to nearly 15*l.* for each student) has each year to be made up by the State.

AT the half-yearly meeting of the court of governors of Owens College, Manchester, held on Tuesday last, the following resolution was carried by a majority of two:—"That, subject to such limitations and conditions as the council may from time to time determine, and subject to the council being able to make satisfactory provision for a separate instruction in such cases as the council consider necessary, the court is of opinion that it would be desirable to admit women students to the course of study which would qualify them for medical degrees and practice."

ACCORDING to the Allahabad *Pioneer Mail*, during the past year no fewer than 11,000 candidates presented themselves for the various examinations of the Madras University, and of these slightly over 4000 were successful. The fees paid by candidates amounted to nearly Rs. 1,87,000; while sundry items, including about Rs. 10,000 interest on Government securities, swelled the income of the University to a little over two lakhs of rupees. The total expenditure for the year came up to Rs. 1,80,000, of which sum Rs. 1,38,000 were absorbed by examiners' fees. The Arts Examinations, as usual, yielded the greatest portion of the University income—the total fees realised from candidates amounted to over one and a half lakhs of rupees, while payments to examiners came up to Rs. 90,000. The Law Examinations yielded a quarter of a lakh of rupees, while the examiners fees only amounted to slightly over half this sum. The Medical and Engineering Examinations, however, are conducted at a loss; but, after balancing receipts and expenditure, the University realised a net profit during the past year of Rs. 10,000, without reckoning the Rs. 10,000 accruing as interest from Government securities.

WE learn from a memorandum that has just reached us that the number of students who attended the City and Guilds of London Institute Central Technical College last session was 245. Of these 220 were following the Diploma Course, eighty-eight attending the First Year Course, seventy-eight the second, and fifty-seven the third. Twenty-five other students were either engaged in research work or were following a special course. During the past year the council has conferred the diploma of Fellowship of the City and Guilds of London Institute upon two of the past students: Mr. W. J. Pope and Mr. A. E. Childs. Siemens Medals were awarded to Mr. F. E. Whittle and Mr. F. C. Hounsfield. Mr. T. M. Lowry and Mr. E. C. Jee, were successful in gaining the D.Sc. degree of the University of London for research work done in the Chemical Department of the College. Twelve students of the College were successful in passing the intermediate B.Sc. examination of the London University. In addition to the students admitted on the results of the Matriculation examination, several others have been admitted to special courses of instruction, and the number in the College at the commencement of the new session will be about 260. Those in special courses number 20. As built the College was intended to accommodate only 200 students. To make adequate provision for Electrical Engineering, a large portion of the basement floor in the adjoining new building of the School of Art Needlework is to be used. The suite of rooms now occupied by the Technological Examinations Department will also become available for teaching purposes, as more extensive quarters are to be found for the Examinations Department in the new building. In connection with this institution, our readers may be referred to the address delivered to the students by Sir Andrew Noble, K.C.B., F.R.S., on Tuesday last (see p. 551 of the present issue).

WHEN the history of education in rural districts comes to be written, the school of science established by the united efforts of the Countess of Warwick and Prof. Meldola, at Bigods, near Dunmow, in Essex, will be given an important place in it. The claims of science to form a part of every national system of education are becoming more and more recognised in our cities, but the forward movement has not been much felt in rural districts, hence the school at Bigods is of the nature of an experiment, and much depends upon the success attained. The curriculum followed in the school meets the requirements of modern education in a most efficient way. The school is a continuation or secondary one in which the ordinary "humanitarian" subjects are by no means neglected, but are carried to higher stages. Modern languages are included, and grammar, geography and history find their places. But the noteworthy characteristic of the school lies in the fact that students devote fifteen hours a week to science, which is not taught in the old-fashioned way, by means of books and blackboard and chalk, but by real work and by observations carried on by the pupils themselves in the laboratories and in the fields. The reasoning faculty is developed by scientific methods at the very commencement of the pupil's education at the school; and students who stay at Bigods for three or four years will have acquired knowledge which will be of the highest value in after life, whether they pass into an agricultural college or enter at once into rural or other industries. For the sake of British agriculture, it is to be hoped that parents in East Anglia will appreciate the efforts being made at Bigods to provide a system of education which will assist both individual and national progress.

## SOCIETIES AND ACADEMIES.

### PARIS.

**Academy of Sciences**, September 25.—M. Maurice Lévy in the chair.—Studies on trimethylene, by M. Berthelot. Preliminary experiments were made on the preparation of trimethylene in the pure state, free from propylene, and the gas obtained, believed to be pure, was characterised by its slow reaction with bromine. Propyl alcohol dropped upon hot zinc chloride gives propylene mixed with hydrogen and propane, but almost free from trimethylene; isopropyl alcohol behaves similarly, and the substitution of strong sulphuric acid for the zinc chloride does not result in the formation of any trimethylene.—On the Neomylodon, by M. Albert Gaudry. An account of the discovery of fossil remains in a cave in Terra del Fuego by Dr. Otto Nordenskjöld, the chief being the skin of a large animal resembling the Mylodon, and which has been named Neomylodon by M. Ameghino.—An account of the ceremony organised at Como to celebrate the discovery of the galvanic battery by Volta.—Observations of the sun made at the Observatory of Lyons with the 16 cm. Brunner equatorial during the first quarter of 1899, by M. J. Guillaume. The results are expressed in three tables giving the number of spots, their distribution in latitude, and the distribution in latitude of the faculæ.—A comparison of the times obtained for the contacts of partial eclipses of the sun by direct observation and by measurements of the lengths of common chord, by M. Ch. André.—On fixed transformation points, by M. H. Le Chatelier.—On the diurnal variation of atmospheric electricity, by M. A. B. Chauveau. From the results of observations made at the summit of the Eifel Tower, it is found that the true law of variation is given by a simple oscillation with a maximum in the day time, and a very constant minimum at 4 to 5 a.m. The more complicated curve obtained by observations in an ordinary building are probably due to the influence of water vapour.—On a particular mode of reproduction of appendices of insects in course of regeneration after artificial section, by M. Edmond Bordage.—On the lateral cephalic organs in *Glomeris*, by M. N. de Zograf.—Some phenomena of cellular disorganisation, by M. Vital Boulet. The asmotic pressure in the cells of a leaf severed from the plant and left in the same water as that in which the original plant was growing was found to regularly increase from 2·2 on the first day to over 6·0 on the twenty-second day.—On the formation of secreting canals in the seeds of certain species of *Garcinia* and *Allanblackia*, by M. Édouard Heckel.

THURSDAY, OCTOBER 12, 1899.

## VERWORN'S "GENERAL PHYSIOLOGY."

*General Physiology. An Outline of the Science of Life.* By Prof. Max Verworn. Translated from the second German edition by Dr. Frederic S. Lee. Pp. xvi + 615. (London: Macmillan and Co., Ltd., 1899.)

WE cordially welcome the appearance of an English translation of this well-known book. The first (German) edition appeared in 1894, and was noticed at some length in this journal (vol. li. p. 529). The in erest which it excited is testified to by the practical fact that a second edition in German was called for in 1897, while translations into English, Italian and Russian have also appeared.

The second edition differs from the first only in detail. The general plan remains the same, though, as the author remarks in the preface, the more important results of the very large number of researches in the physiology of the cell which have appeared during the last few years have been added.

The scope of the book is "an attempt to treat general physiology as general cell-physiology," and thus to outline a field in which the various branches of special physiology might unite. The author is at some pains to define the cell as the unit of organised living matter—the smallest part which can maintain an independent existence; it is the "elementary organism." Having described this unit, and discussed its structure and chemical and physical constitution and the way in which the substance of which it is composed differs from non-living substance, the author proceeds to a consideration of the phenomena which are manifested by cells in general. He is thus led to a discussion, firstly, of the internal phenomena of life in their most general aspect—of change of substance or metabolism, of change of form, and of change of energy; and, secondly, of the external relations of living matter, of food, of effects of temperature, &c., of stimuli, of the origin of life on the earth, and of the process of dying. Lastly, he returns to a consideration of the nature of the material of the cell, and seeks there an explanation of these internal and external phenomena. These inquiries are sufficiently wide; but the author, not content with them, includes an interesting history of physiological research, in which he rightly endeavours to justify his own standpoint by an appeal to the development of the science; and a discussion, in true Ercles vein, of the relation of physiological research to metaphysics in which, among other things, the investigator is invited to "get rid of the error of the existence of a physical world outside the mind"!

Those who have made acquaintance with Prof. Verworn's views in other and earlier publications, as, for instance, in papers published in the *Monist* (*cf.* NATURE, li. p. 58), will not be surprised to learn that the tone of the book is somewhat aggressive. He has set himself the task of recalling physiologists from the barren field of "one-sided specialisation," whatever that may mean, to a renewed consideration of the ultimate problems of life. He is impatient with the "impotence of the physiology of to-day in the presence of the simplest vital processes." The outworks are down, why do the workers stay prying into the ruins when they should press on to attack the central citadel, the cell, wherein the simple secrets of these simplest of processes are hidden?

No fault can be found with the purpose which is outlined here, but unfortunately the reader's sympathies are apt to be lessened by a lack of restraint and reticence in the advocacy. There is an unpleasant tone of special pleading running through the pages, which inevitably raises the suspicion that the author's outlook is perhaps not so broad as he would have us believe.

A good wine needs no bush, and the virtues of an endeavour to bring together all that is known of the general properties of living matter suffer when heralded by an impeachment of the past achievements of physiology which is phrased so as to convey the idea that the nature of the processes which constitute life has not been touched on. In point of fact, the knowledge gained, amongst other things, of the internal respiration of muscle, of the automatic phasic activity of the cardiac and other tissues (due, by the way, mainly to the work of Gaskell, and not to that of Engelmann, as the author states), and of the special processes of storage and discharge in glandular organs, has led to a first approximate conception of the character of the changes, both in matter and energy, which waits for further development, not upon the labour of biologists, but upon that of workers in the domain of molecular physics.

It is possible that the central idea of the book—the assertion of the identity of general physiology with cell physiology—is founded upon a misconception, and we are inclined to doubt whether any special virtue is likely in the future to flow from the study of the cell. If the cells in question form part of tissues or organs, then the methods are the methods which have been employed in the past. The study of the cardiac muscle cell is the study of the heart, of the secreting cell that of the gland which holds it, and so on. Practically, as one learns by perusing Prof. Verworn's pages, what is really new in his method is confined to the exaltation of the importance of the study of the cell when it is an independent individual, such as one finds in the members of the Protozoa. In this field he has himself laboured with no small measure of success. The phenomena exhibited by free-living cells are unquestionably of surpassing interest, but, unfortunately, the study of the relatively diffuse activities which they manifest must be of secondary importance, seeing that the facts which are gleaned can only be interpreted by the aid of that insight into the finer anatomy of function which springs from a study of the highly specialised organs of the higher types where the activities of living matter are, as it were, analysed for us.

This is not the only drawback. There is another, and perhaps more serious one, which the author nowhere stops to discuss. It lies in the difficulty which exists when minute forms are used for experiment in deciding how far a given result is a true physiological reaction to a stimulus, and how far it is a purely mechanical effect. For instance, under the heading of galvanotaxis, and in the section dealing with the general effect of electrical stimuli, a description is given of the way in which animalculæ become grouped round one of the poles, while individuals suffer actual alteration in shape under the influence of a

 B B

constant current. But, as Faraday was the first to show, small particles of any kind are driven to one or other pole when suspended in fluid through which a current is passed, and a rod of jelly suffers compression at one end and expansion at the other under the mechanical stresses produced by the passage of a current.

The general tone of the book is inspired by an impatience with the laggard pace of knowledge—the "foster-child of silence and slow time," if one may wrest a phrase of Keats from its setting—which prompts the taunt that the physiology of to-day is impotent in face of the simplest vital processes. Unfortunately, it is not controlled by a true feeling for the relation of the knowledge of living matter to the progress of the general knowledge of matter. The tools with which the attempt to fashion a dynamical explanation of the phenomena of life must be made are themselves still in the making. It is barely ten years since what was practically the new science of molecular physics was founded at the meeting-place of chemistry and physics by the labours of Guldberg and Waage, Arrhenius, van 't Hoff, Gibbs, Ostwald and others. On the growth of this science the biologist must wait, and, though the advances which it has made are prodigious, they are concerned wholly with the crystalloid type of matter—they have not yet embraced the colloid type which is the physical basis of life.

The completeness of our ignorance of the latter type is manifested with almost dramatic force when one finds all that is known of colloidal matter lying in the compass of a page or two of a text-book such as that of Ostwald or of Nernst, whereas the account of the crystalloid type stretches to many hundreds! Reproaches and hasty generalisations are equally out of place in the face of this colossal ignorance of the elements of the problem; and one feels the practical wisdom of physiological workers in devoting themselves to what may be called the anatomy of function—that is, the interpretation of organ and tissue activities in terms of the fundamental properties of living matter, rather than in kicking against the barriers which the general state of knowledge opposes to the translation of these fundamental properties into terms of matter and motion.

The same lack of a sense of the historical position of biology caused Bunge to drift into vitalism, which at any rate has the merit of recognising the difficulties which stand in the way of a dynamical explanation of metabolism, irritability, and the recurrent cyclic character of the phenomena of life.

Prof. Verworn, however, is impelled to the opposite extreme—a materialism, often rash, which leads him to a disastrous quest for "simple explanations," in which his knowledge too frequently becomes wire-drawn to the breaking point. The "mechanical explanation" which he offers of the "so-called" selection of food will serve as an instance. A cell bathed by a nutrient fluid such as, *e.g.*, an epithelial cell absorbing material from the lumen of the intestine, is likened to a crystal growing in its mother liquor. Like its analogue, it withdraws only special substances from the common nutrient fluid, "as is evident from the fact that gland, muscle and cartilage cells produce wholly different and characteristic substances." Hence the conclusion that the selection of food is only a special manifestation of chemical affinity, and that "it is an absolutely necessary consequence of the fact that the living substance of every cell possesses its own specific composition and its own characteristic metabolism." So in place of the healthy recognition of a difficulty we are offered a cumbrous platitude and a leap in the dark!

The simple explanation which is offered of the fact "which must otherwise appear very wonderful" (*sic*), that among the innumerable swarm of spermatozoa cast into the sea, every species finds its proper ovum, also deserves mention. It "is explained very simply by the further fact that every species of spermatozoon is chemiotactic to the specific substances that characterise the ovum of the corresponding species." The robe of modesty is more fitting than the gown of counsel for explanations like these!

In other cases the haste for simple explanations leads to a mode of treatment of problems of acknowledged difficulty which intensifies the obscurity. Thus some space is devoted to urging that there is no distinction between the motor impulse or the electric current in their action upon, for instance, muscle fibres and that relation between motor nerve cell and muscle fibres which, when it is broken by severance of the connecting nerve, causes degeneration of the latter. This view is distinctly opposed to the results of recent work upon muscular tone, and upon the effects of section of the roots of spinal nerves which tend to emphasise the distinction between the calling out of special activity by special nervous impulses and the fact that many highly specialised cells are dependent for their continued well-being, even for their capacity to respond to stimuli, upon their functional continuity with other and totally dissimilar cells. We are ignorant of the nature of the latter relation, though it may well be one of simple dynamical equilibrium rather than one dependent upon the passage of nervous impulses. But Prof. Verworn starts in a panic from this unsolved problem. He sees in it a piece of the old mysticism of the vitalists, and, in order to compass a simple explanation, trophic relations are grouped with the action of electric and chemical stimuli and of food into one class which lacks both order and form.

In spite of these defects in general tone, the pages of the book furnish abundant justification for the success which it has already attained. The point of view which the author has adopted has led him to bring together a body of facts, many of them little known, in a manner which cannot fail to be stimulating and suggestive to both physiologists and morphologists. Many gems of thought, too, are to be found, especially in the later chapters. The sections on the directive effects of unilateral stimulation, chemiotaxis, barotaxis, &c., are singularly interesting, and so too is the conclusion which is drawn from the facts, namely, a general application of the principle of the specific energy of sense-substances.

> "All living substance possesses specific energy in Müller's sense: with certain limits wholly different stimuli call forth in the same form of living substance the same phenomena, while, conversely, the same stimulus in different forms produces an effect wholly different and characteristic for every form."

The treatment of the dynamics of movement as a polar change in the resultant of the anabolic and katabolic processes in the cell, or "biotonus," as the author calls their algebraical sum, is equally illuminating, as are also parts of the mechanics of cell metabolism.

The pages dealing with actual facts, which after all make up by far the greater part of the book, possess an enticing feeling of freshness and novelty which is born of the fact that the author's special studies have lain out of the beaten track. For this and for the intrinsic interest of the facts themselves we feel grateful to him, and we heartily wish success to the English edition. The translation bears abundant evidence of the care which Prof. Lee must have lavished upon it. It is a monument of clearness throughout. W. B. HARDY.

## OUR BOOK SHELF.

*Living Pictures.* By H. V. Hopwood. Pp. xii + 275. (London: *The Optician and Photographic Trades Review*, 1899.)

THIS is a very interesting review of the gradual evolution of the various instruments which have been invented for the portrayal of objects in motion, from the earliest times to the present day. The work may be divided into two parts, of which the first, including Chapters i.–iii. (pp. 1–109) deals with the more distinctly historical aspect of the subject, while the remaining chapters (iv.–vii.) are devoted to a very minute description of all the important machines in present use.

Chapters i. and ii., on the "Persistence of Vision," &c., contain a lucid account of the principles governing the phenomenon of a succession of different views of the same object giving the impression of the object being in motion. In this part all the instruments, whether as toys or scientific apparatus, are described in the order of their invention, beginning with the simple colour tops and thaumatrope put forward as early as 1826. The host of improvements from this time up to about 1878 were attempts to remedy the difficulty of so small a percentage of light passing the two slits at first used for the intermittent view. This section concludes with descriptions of the modern mutoscope and viviscope.

Chapter iii. (pp. 43–109) commences with the invention of "chronophotography," and gives a complete description of the more important of the inventions brought out from 1865–1895. The mechanical details in connection with the alternate exposure and movement of the sensitive surface receive special attention, the difficulty of following these being greatly lessened by the numerous illustrations accompanying the text.

Chapter iv. is devoted to present-day apparatus, and all the machines which have appeared before the public receive ample notice, in most cases accompanied by a woodcut showing the internal arrangements.

Chapters v. and vi. deal with the processes adopted in making the films, their exposure, development, printing, &c., and also give ample practical instructions for exhibiting the pictures in the lantern.

At the end of the volume two most useful appendices are given. The first is a "Chronological Digest of British Patents," giving a short *résumé* of all specifications taken out in connection with living pictures from the time of Fox Talbot (1851) to the end of December 1898.

The second appendix is an annotated bibliography of all publications (British and foreign) from 1825 to the present time, which bear on the subject.

The numerous illustrations (242), which are well chosen and very clearly printed, render the following of the necessarily somewhat technical matter exceedingly interesting even to the non-expert. The book will be welcomed by many to whom the methods of cinematography are a mystery, as by its aid any one even strange to the subject may easily understand the working of any of the machines in past or present use.

*Tables and Data.* By W. W. F. Pullen. (Manchester: Scientific Publishing Company, 1899.)

IN these eighty-seven pages Mr. Pullen brings together tables and data which will be found very serviceable in engineering laboratory work and in the solution of class problems and exercises in mechanical engineering. Points perhaps of special mention are that the general steam table is carried up to 300 lbs. per square inch; the diagram for determining the dryness of steam with the throttling calorimeter is plotted on a large scale, and the melting points of various substances has been revised by Sir William Roberts-Austen. For facility of reference the British and metric measures are placed side by side. The remaining portion of the book is devoted to mathematical notes on mensuration, geometry, trigonometry, &c., with a synopsis of mathematical data. At the end are added a few extra pages, some of which are blank, while on others are printed diagrams of millimetre paper, for the insertion of any additional curves the student may wish to insert. Not only engineering students, but others should find the contents of this book a useful laboratory *vade-mecum*.

## LETTERS TO THE EDITOR.

*[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.]*

### Halo Round a Shadow.

IN your issue of this week Prof. S. Newcomb draws attention to the halo which an observer often sees round the shadow of his own head when the ground on which the shadow falls is covered with vegetation or any obstructions which can themselves cast shadows.

In a letter to NATURE in 1878 or 1879 (I have not the reference by me) I mentioned this phenomenon, giving the same explanation as your recent correspondent, and adding that the angular width of the halo was settled by the ratio of the mean diameter of the obstructions to their distance from their own shadows.

The halo (or spot of light, if the observer is too far off for his own shadow to show) can be seen very well when the ground is covered with heather or bracken whose twigs and leaves are small compared to their height above the ground.

3 Victoria Street, S.W., October 6. A. MALLOCK.

### The Skull of Hatteria.

IT may be worth while to draw the attention of naturalists to an omission in the figures of the skull of that archaic reptile, the Tuatara, that occur in two recent text-books of somewhat wide circulation, viz. Parker and Haswell's "Text-Book of Zoology" and Reynolds's "The Vertebrate Skeleton." These figures are either copied or redrawn from Zittel's figure published in his well-known work on Palæontology. This figure appears to have been drawn from an imperfect specimen, as the "transverse" (or transpalatine) bone is omitted in the ventral view; it is *apparently* represented in the dorsal view, however, though there is no index line in the original. The bone, though of considerable size, very readily drops out of a thoroughly macerated skull, from which the figure was no doubt drawn. There is really no excuse for our English authors borrowing the figure from a German book in this instance, for Dr. Günther's picture of the skull published in the *Phil. Trans.*, vol. clxvii., is perfectly accurate, except in regard to nomenclature of some of the bones, while Zittel's is most indistinct.

Dunedin, N.Z., August 30. W. BLAXLAND BENHAM.

## *THE BEST EDUCATION FOR AN ENGINEER.*[1]

An admirable address, well thought out, well delivered, and received with bursts of applause, which were so enthusiastic that they sounded like volleys of musketry. We are still in the early days of the history of technical education, and such deliberate expression of opinion by those who are connected with the engineering industry are much needed on the subject of the early training of the engineer; and when the speaker is Sir Andrew Noble, in whose works 30,000 gain their living, and when, in addition, he says what he really thinks, and does not merely confine himself to complimentary remarks about the College in which he is speaking, his address cannot fail to command close attention.

On two important occasions captains of industry, when referring to the early education of those who afterwards go to the City and Guilds Technical Colleges, have enlarged on the value of a classical training—Mr. Alexander Siemens in 1892, and now Sir Andrew Noble. Now, why is this?

A considerable proportion of those who have made their mark undoubtedly received a classical education, but one asks, Was it the classical education that made them famous, or was it their great natural ability, and consequent success, that made the reputation of classical education? Or is there some other and deeper reason for this advocacy of the study of the language and literature of the peoples who, near the beginning of our era, occupied a small portion of the earth as we now know it? Not certainly the argument so frequently urged—urged even by Sir Andrew Noble in this address—that a student of science should study classics to better understand the meaning of scientific terms. This will teach him that "geometry" means "land surveying," and leave him disappointed that six books of Euclid do not enable him to measure an irregularly shaped field; his Greek will tell him that a "logarithm" is a "proportion number," but a book of them will still be Greek to him. That it is a mĭcrophonē that is used in sending a message to a tēlĕphonē will provoke a laugh from the man in the street, and if to a knowledge of classical grammar the student of science adds that of his own language, he will realise that one reason why it is so difficult to obtain a "reliable" measuring instrument is because such a thing is impossible, for the verb "to rely" must be followed by the preposition "on."

No! such a utilitarian argument in favour of classical study is rather a confession of weakness. Nor—as is so often alleged—is a classical study of importance because it facilitates the learning of modern languages. For many are the Dutch, the Poles and the Russians who talk with exasperating volubility in one's own language, wherever one may have been born, but who know less Greek and Latin than an Eton boy whose linguistic powers are as insular as himself.

A study of the classics and a public school education are frequently regarded as synonymous, and so the advantages of the one are confounded with the advantages of the other. At the present time, when so much attention is devoted in secondary and technical schools to *matter* rather than to *manner*, when the aim apparently is to turn out scientific encyclopædias rather than fairly well-informed people with cultivated manners, the following opinion expressed by Sir Andrew Noble should be taken to heart by every engineering student:

"Speaking as an employer of labour, I should say that we find a pleasant speech and manner, tact in dealing with others, and some power of organisation of the utmost value; and it is precisely those qualities which a boy acquires, or ought to acquire, in his *later* years at a public school. Without such qualities even the highest scientific attainments will never make a captain of industry, and in selecting candidates for appointments the man of business distinctly prefers a youth who has had the benefit of some years at a good school."

But this polish, we urge, might equally well be acquired were the study of Japanese or the production and use of the electric current, or the action of mechanical forces, substituted by a *thoughtful* teacher in a public school for that of Greek and Latin. For that cultivation, which we all value so highly, is not produced by the association of a lad with *dead* writers of exceptional ability, but with *living* lads of his own standing, coming, like himself, from homes where refinement and right feeling pervade, and all, like himself, bent on preserving a tradition which, though sometimes foolish, sometimes rough or even brutal, still tends on the whole towards civilisation. It is not so much the *study* as the *life* of a public school boy that is so valuable in forming his character.

But if that be the case, is Sir Andrew justified in deducing the following conclusion?

"My own impression with regard to early education is that, as a sharpener of the young intellect, and as a mental discipline, it would be difficult to improve upon the curriculum which is now in force at our public schools, and which, in the main, has been in force for so many centuries."

The curriculum of a public school is, we think, not exempt from the rule that what man has devised can always be improved. A classical education, the staple of the public school curriculum, has undoubtedly the great advantage that some of the greatest thinkers in the past spent the early part of their lives in receiving it, and the latter portion in giving it to others. It is, therefore, the particular form of training that has been carefully thought out, and its development is the result of long years of trial and error. Further, it possesses another advantage, the value of which does not seem to have received the recognition it deserves, and this is that when the merest dullard is puzzling out some passage with the aid of dictionary and grammar, he is really engaged in a small way on precisely the same kind of work that enchants the greatest scientific investigator, viz. finding out for himself something that he wants to know.

Now this by no means characterises the work of all the students in a well-fitted modern laboratory. Not a few, following the instructions, spend hours taking readings of instruments and tabulating the results, but fail to find out what is the meaning of these results, or even what is the object of the experiment itself. They have, in fact, been laboriously grinding at the handle of the barrel organ, but have been mentally deaf to the tune that it played.

Heartily then do we join with Sir Andrew Noble in deprecating training of this kind—whatever it may be called—and agree with him that even when all technical study is postponed until after school and college life:—

"Those men who, with fair abilities, have received a really good education, have been taught to use their minds, and who, by contact with other students, have acquired habits of application, amply make up for their late start by the power of mind and grip that they bring to their work."

But can these qualities, we ask, only be acquired by confining a boy's attention to the study of words and ideas, and by excluding all study of nature and things? Sir Andrew himself states:—

"In nine cases out of ten, I should say, any knowledge acquired by a boy before he is sixteen can have but a slight intrinsic value. Up to that age, it is not *what* he learns that we have to look at, but *how* he learns; it is the habit of discipline, of mental application, of power in attacking a subject, that are so valuable; not, generally, any definite piece of knowledge he may have gained."

Now surely "the habit of discipline, of mental application, of power in attacking a subject" is exactly what

[1] Inaugural Address of the Session 1899-1900 of the City and Guilds Central Technical College, given at the College, Exhibition Road, by Sir Andrew Noble, K.C.B., F.R.S., on Tuesday, October 3.

can be learnt from a *proper* study of science, and, so far from any knowledge acquired by a boy before he is sixteen having but a slight intrinsic value, is it not a fact that all knowledge requiring mechanical dexterity, such as reading, writing, arithmetic, riding, swimming, talking foreign languages, playing a musical instrument, &c., can be far better acquired before the age of sixteen than later, and are not all these examples of knowledge possessing intrinsic value?

We are, however, quite at one with Sir Andrew in thinking that

"the age at which a boy should seriously begin any special studies, with a view to fit him technically for the profession he may have decided to follow, should not be earlier than seventeen or eighteen."

But should not a sharp distinction be drawn between learning technology and acquiring the elementary principles of science? His warning that the zest for your life's work may be weakened by embarking on it too early certainly furnishes a potent, probably the most important, reason why lads who intend to become engineers should wait until they are eighteen, or at any rate seventeen, years old before they commence their professional education; for then, as is said in the address, they will be

"fresh and keen when others, who have been hammering away at semi-technical work from early boyhood, have become stale and are less vigorous."

For the same reason also, time devoted by a lad to learning off strings of scientific facts would be misspent, but not so, we think, would time given by even a child to the acquisition of scientific habits of thought. We do not defer teaching a lad the principles of morality until he is seventeen or eighteen for fear he should become tired of living a moral life, why then should the risk that a lad might weary of leading an intellectual one frighten us into excluding the principles of science from a good education?

In the address, "science, mechanical drawing, and such like" are classed together as things that may with advantage be omitted from the training of a lad before entering Elswick, provided he has had a good education. But can an education of the present day be termed "good" which lacks a training in those mental qualities which are classed under the head of scientific?

Great stress was laid by Sir Andrew Noble on the value of the knowledge which a person has gained for himself. He cited the results which "dauntless energy, untiring industry and patient search after truth" had achieved for Lord Armstrong, Watt, Stephenson and Faraday, but only as a proof "that a special technical education is not an absolute necessity." Do not the lives of these men, however, teach us much more than this, viz. that the particular system of education, classical, mathematical, scientific, artistic or technical—in fact, any system of education ever invented—is less than nothing in enabling a man to rise to the top in comparison with the determination to succeed and the brains to do it?

The reason why certain branches of industry have almost abandoned this country, and why new branches that have been developed abroad have hardly taken root with us, is a topic deeply interesting to the manufacturer, but generally rather distasteful to the student, since he would prefer to be told that everything was done better, more cheaply and more expeditiously in his own country than in any other. Sir Andrew Noble, however, made even the part of his address which dealt with this subject appeal strongly to his audience, and for a remedy he thought that it was

"to theoretic and technical knowledge that we must chiefly look. Consider, as an illustration, electricity in the service of man. Think of its innumerable applications, and of the number of hands dependent upon its industries. But for one man capable of designing or improving these powerful machines or delicate instruments, there are a thousand ready and able to carry out their designs. But it is the former who are the salt of the earth, and those who have the management of large concerns know well how to value them."

His patriotic statement (for it is true patriotism to help your own countrymen to learn the truth even if it be distasteful) that the success of our German competitors was *not* due "to their putting on the market inferior goods specially got up to imitate those of a superior class," but "to the far greater opportunities of technical study which are afforded in Germany," was as bold as we believe it to be true. For we were recently informed by an English manufacturer that certain things manufactured in England are now being stamped "Made in Germany," in order to obtain a readier sale for them in our own country.

But in addition to greater facilities being needed in Great Britain for the study of the applications of science to industry, greater belief in the value of such study is wanted, not only on the part of the English manufacturer, but also on the part of the English student. "You younger men," said Sir Andrew, "must do your part by seeking to avail yourselves to the uttermost of any such opportunities provided," and it might be added that the reason why that future "important commercial rival, Japan, is developing its manufacturing powers with an energy that is as remarkable as it is unexampled" is because even thirty years ago its young students absorbed with eagerness and rapt attention every scrap of scientific teaching which they could obtain. And they did so partly for their own personal benefit, but far more because each one felt that on his own exertions depended the fame and future of his mother country. W. E. A.

## RESEARCH WORK AND THE OPENING OF THE MEDICAL SCHOOLS.

IN one sense at least, viz. his intellectual life, the medical student, natural enough in other respects, seems somewhat at variance with nature; his intellectual spring occurs simultaneously with nature's autumn. Brown October sees him change the abstractness of the class-room for the concreteness of the laboratory. Further, each successive autumn, after a period of summer hibernation, marks the advent of some change in his studies. The fully fledged doctor, too, whose daily round obliterates all distinction between term time and vacation, becomes infected in October with a revival of intellectuality, and whets his appetite by an attendance at the inaugural address delivered at his school, where he gets new knowledge or old dished-up afresh, and becomes generally imbued with the spirit of the time.

This year at least the medical student will not be able to lay any shortcomings which may occur during the ensuing academical year to the charge of insufficient or inadequate advice at its onset. At both the London and provincial schools the inaugural addresses, with regard to depth of meaning and also attractive eloquence, have left little to be desired.

In a short article such as the present it would be impossible to adequately reproduce, even in the most abridged form, the various "motifs" pervading the speeches delivered. One, however, constantly recurring, may be somewhat enlarged upon. Here and there and everywhere in the inaugural addresses we find the position of research to medicine and the medical profession cropping up. Occasionally this subject is mooted in the grossly material form, when, for instance, Sir James Crichton Brown frankly told his hearers at Manchester that although 70,000*l*. was an adequate sum so far

Manchester must be prepared to put its hand in its well-lined pocket for an equal amount to keep pace with science, which is now so mobile and so expensive. Dr. Clifford Allbutt delivered an address at St. Thomas's, which mostly consisted of a strictly logical defence of theory and abstract learning. Those who read carefully Dr. Allbutt's address will find more in it even than this. The apostles of empiricism, to whom the almighty fact is alone of importance, are the worst enemies of what may collectively be termed medical research. Their bourgeois utilitarianism prevents them from appreciating or forwarding any branch of inquiry connected with the medical sciences which does not immediately result in something of use. Research to them is the quintessence of an abstractitude.

This mental attitude of a part of the profession, which fortunately is getting less and less, finds its expression in the position adopted by the influential public and lay committees. It is somewhat anomalous—at any rate, it appears so—that astute financiers, practical men accustomed to weigh the chances of ultimate dividends in the most complicated concerns, should so discount pathological and pharmacological research. It must be known to them that a large proportion of the drugs they take, and the curative remedies they employ, are made in Germany, and that thousands of pounds are spent annually on German products of this class which might perfectly well be produced at home. Those of them who wander so far from the Stock Exchange as St. Dunstan's Hill will find there a whole colony of German firms which supply these articles. A public which will wait for years for dividends so far as concerns South African securities, which will fill up readily the gaps in a Cape to Cairo railway scheme, although this at present can only be done by a somewhat lively imagination, is inclined to push and accelerate the scientific worker, and expect maximum results in minimum time. The success of the German manufacturer in products such as therapeutic sera and synthetic drugs is simply due to the fact that the German capitalist has waited for his dividends which he is now getting. Apart from the standpoint of mere commerce, it is somewhat galling to know that a crude product like coal-tar is at present exported from this country, and re-imported worked up in the shape of dye-stuffs and drugs.

To work one must have a workshop; a palace one does not need. This forms another great difficulty with regard to medical research in London. The authorities at the London hospitals rightly regard the patients as having the first charge upon the space and accommodation at their command. Space in London, especially so far as concerns the older foundations—such, for instance, as St. Bartholomew's and Guy's—is necessarily very valuable. This subject formed the keynote of some of the speeches at the old students' annual dinner at St. Bartholomew's. The Great Hall was full of old Bartholomew's men, who, under the chairmanship of Dr. Lauder Brunton and the secretaryship of Mr. Bruce Clarke, met to inaugurate the new academic year. Dr. Lauder Brunton, in a short but effective speech, proudly stated that the hospital, so far as its essentially medical aspect went, left nothing to be desired; quite so much, however, could not be said for the laboratory accommodation. Sir Norman Lockyer, whose opinion upon the subject of experimental technique ought certainly to be final, also deplored this want of laboratory space in so old and famous a medical school. Many difficulties special to medical research were discussed by Sir Norman, and research in this branch of knowledge was compared to research in the physical sciences. One of the difficulties was the question of time. The worker in the fields of the medical sciences must solve his problems often at once. He must be an opportunist. Stars and planets remained more or less the same, but this was not so with disease. Pressure from without, according to Hunter, causes hypertrophy or overgrowth, pressure from within atrophy or waste. If the pharmacological laboratory at St. Bartholomew's is not in a condition of healthy overgrowth, it is certainly not because pressure from without is wanting, for, according to Dr. Brunton, its confines have been narrowed down to some fourteen square feet. It was reassuring to be informed by the treasurer, Sir Trevor Lawrence, that arrangements were on foot which would ensure more ample accommodation to laboratory workers at Bartholomew's.

The London Hospital was fortunate in securing the presence of Dr. Haffkine, who made an excellent and humorous speech. The St. George's students were addressed by Dr. Howship Dickinson upon "Medicine Old and New." Dr. Mitchell Bruce, at Charing Cross, took the "Outlook of Medicine" as the subject of his address. This was, he said, at the present time hopeful, since the scientific method was being pursued in every department of medicine.

In laying stress upon the special difficulties of the time, one is perhaps rather apt to forget the causative origin of all the inaugural addresses, viz. the medical student himself. He comes in ample numbers, a sufficient testimony to the healthiness of the profession he aspires to join, from year to year, sometimes partially prepared by the universities, sometimes raw from school, to struggle with those life-long difficulties of the healing art, compared to which even examinations count as nothing. For five years, now, he must suffer many things of divers examiners, and finally emerge to meet the great problem of his life—the human individual, both healthy and diseased. Exact knowledge in the sense of physical exactitude will probably be denied to as yet many generations of medical students, even concerning the main problems of disease, and in spite of the progress that, thanks mostly to careful and continual laboratory work, often of an apparently abstract nature, has during the last century been made, our knowledge even now serves often merely to illuminate our ignorance, and however optimistic our hopes for the future we are forced to admit that—

A thousand things are hidden still,
And not a hundred known.

F. W. T.

## DARK LIGHTNING FLASHES.

IS there such a phenomenon as dark lightning? This is a question that has often been raised, and as yet no satisfactory answer has been given. If dark flashes do really occur, then they should probably be both seen and photographed, and the former, one would think, would be the more simple way of recording them. A difficulty, however, here arises, for if we assume that both dark and bright flashes occur during a thunderstorm, then we must be careful not to mistake retina-fatigue dark flashes for actual dark flashes if they exist. Lord Kelvin (NATURE, vol. lx. p. 341) has lately pointed out how, during a recent storm, he was able to confirm the existence of these *apparent* dark flashes; and in a more recent number of this journal (vol. lx. p. 391) I published some observations corroborating the same view. It must be pointed out, however, that, although such observations indicate that the majority of dark flashes seen may be attributed to the cause of fatigue of the retina, it does not necessarily follow that dark flashes do not actually occur. Eye observations, therefore, do not help us as yet to give a satisfactory answer to this question.

Let us turn now to photography, and see what evidence we can gather from photographs of flashes taken during thunderstorms.

In dealing with this mode of recording flashes, we are

again confronted with many difficulties, for the action of light on the sensitive film is capable of giving us both bright and dark images, although the object photographed is bright. We have, therefore, to contend with reversals, double reversals, &c., and many as yet unknown factors.

There is one point, however, that stands out foremost, and that is that the photographic plate has recorded many times dark as well as bright flashes; but whether the dark flashes are due simply to some action relative to the sensitive film, or are actual images of real dark flashes, is the very question that has so recently been revived.

What we really are greatly in need of is more data, and when a sufficient number of photographs of all kinds of lightning has been collected, more light will be thrown on this subject. Up to the present time, as each curious photograph of dark lightning was published, suggested theories as to the cause of the peculiarity of the flash have been by no means few in number, so that now the number of hypotheses equals, if not exceeds, that of the photographs examined.

In a very interesting article in this journal (vol. xlii. p. 151), which is an extract from a lecture on "Electrical Phenomena in Nature," delivered by Mr. Shelford Bidwell at the London Institution, the so-called "dark flash" is referred to in these terms.

"It occasionally happens that, on developing a photographic plate which has been exposed during a thunderstorm, the image of a lightning flash comes out black instead of white. . . . There is no need to discuss the several ingenious hypotheses which were suggested in explanation of the anomaly; it is sufficient to say that the mystery was completely cleared up a few months ago by the experiments of Mr. Clayden."

As I have no reference to Mr. Clayden's experiments at hand, I will quote from the above-mentioned abstract a brief summary of his hypothesis as described by the same writer.

"If the lens of the camera be covered the moment after a flash has occurred the developed image will always come out bright, feebly or strongly, according to circumstances. If, however, the plate be exposed after a flash has acted upon it, either to the continued action of a feeble diffused light or to the powerful glare arising from one or more subsequent flashes, then on development the image of the original flash will probably come out black. The effect is therefore not a meteorological or physical one, but purely chemical. It can be obtained, not only with a lightning flash, but also with a machine spark, or even with an ordinary flame. It is merely necessary that the plate should be exposed to the action of a certain amount of light after it has received the impression and before development."

At the present time Mr. Clayden's explanation may be looked upon as the most reasonable working hypothesis for future use. There is one crucial test which can be tried, which would settle once and for all its value. Unfortunately, so far as I am aware, this test has not yet been made, and I propose (and I hope others will as well) under the next suitable conditions to make the attempt. It is simply this. Take two cameras, say A and B, and orient them both in the same direction towards the point where the same flashes will come in both fields of view. Expose A for say fifteen minutes to record all the flashes that occur during that interval (some of these on development should be *bright*, some *dark*). Expose B for one flash only, preferably the first bright one which occurs during the exposure of A; this should develop *bright*. Compare the same flash on both negatives; that in A should be dark, that in B bright. If this be not the case, then I think the hypothesis breaks down. Perhaps this experiment may not be so easy to perform as it at first appears, for the difficulty lies in being able to catch one strong flash without exposing the plate to any light from other flashes which illuminate the sky, but are not in the field of view themselves. Several attempts by numerous observers would probably give us the information required.

With the object of firstly contributing data towards the interpretation of this curious and interesting phenomenon as recorded by the sensitive film, I give here some illustrations from absolutely untouched negatives of lightning flashes. All these reproductions are reduced about one-third.

FIG. 1.—Lightning flashes taken during a thunderstorm at Göttingen, Germany, in 1893.

I may perhaps preface my descriptions of the photographs by the remark that, having always taken a great interest in procuring lightning flashes by the aid of the camera, I have never, until this year, been fortunate enough in securing records of dark flashes. I have always previously exposed my plates or films for periods of fifteen minutes or more, depending on the strength and nearness of the storm. This fact at first suggested to me the idea that dark flashes might after all be real, but restricted to certain kinds of storms, the special peculiarities of which I cannot state.

FIG. 2.—Showing dark (A and B) and bright (C and D) flashes photographed at Westgate-on-Sea on August 5, 1899.

Fig. 1 is a type of several negatives I have secured previous to this year, and although the exposure was twenty-five minutes in length, an examination of the negative shows absolutely no trace of any *dark* flash. The photograph, which was taken at Göttingen in North Germany, is interesting on account of the fine flash (A) which is traversing the air in a nearly horizontal direction and without any branches or ramifications. In the right-

hand corner will be noticed numerous flashes from clouds a great distance away.

I will now describe three of the four photographs I secured during the storm that passed over Westgate-on-Sea, Thanet, during the night of August 5 of this year (see letter, NATURE, vol. lx. p. 391); all four show

FIG. —Showing bright (B and D) and dark (A and C) flashes photographed at Westgate-on-Sea, on August 5, 1899.

dark as well as bright flashes. The camera employed was one of those excellent and handy little 5 × 4 day-light folding Kodaks, and the exposure in each case was fifteen minutes. The storm, I may add, passed roughly from S.E. towards N.W., and my camera was placed on a window-sill facing due north.

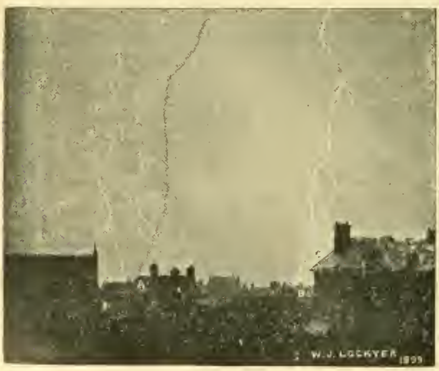

FIG. 4.—Showing bright (B and C) and dark (A) flashes photographed at Westgate-on-Sea, on August 5, 1899.

Fig. 2, showing the north-western sky, displays several flashes, the most prominent of which are C and D bright and A and B dark. The bright flashes have no ramifications, while the dark distinct flash A has several dark. It may be that B is only a large ramification of A, but it is difficult to say.

Fig. 3. The northern sky as here shown displays four prominent flashes, A and C dark and B and D bright. B, as will be noticed, appears to take a very circuitous path, which resembles very closely that illustrated in a previous number of NATURE (vol. xlii. p. 152), and which was a reproduction from a photograph taken on June 6, 1889, by Mr. Rose at Cambridge.

The last, and, I think, absolutely unique photograph of

FIG. —Enlargement of dark flash A in Fig. 4.

a dark flash, is illustrated in Fig. 4. The negative was exposed when the storm was perhaps just a little north of my position (camera pointing due north). The two most prominent flashes are those marked A and B. B is the ordinary bright flash with numerous bright ramifications, while A is also equally, if not more, strong but *dark* with *dark* ramifications. An enlargement of this flash is shown in Fig. 5. Most interesting,

however, is the *reversal*, which extends nearly the whole way up the centre—that is, the dark flash has along its centre a bright core. It is this very photograph which made me cast doubt on the hypothesis suggested by Mr. Clayden, for both a very strong flash can be recorded *very* dark (with a reversal), and also a weak flash (see Fig. 2, B). If the reader refers to an interesting article on "Lightning," by Mr. Jeremy Broome, that appeared in the January number of the *Strand Magazine* in 1897, there will be found a reproduction of a photograph taken at Cambridge by Messrs. Valentine Blanchard and Lunn, showing a *bright* flash with a *dark* reversal down the centre, the exact opposite to the flash recorded above. It may be remarked that a reversal is perfectly distinct from a double flash, many of which have been recorded.

Another flash of interest and peculiarity is that marked C. This flash is quite distinct from B, but unlike all the other bright flashes of about the same intensity, which are clear and sharply defined, this one is occasionally split up along its path into two parts, and the *flash on both sides throughout its whole length is bounded with dark borders.* Both the original negative and a silver print show this peculiarity distinctly, but unfortunately the dark borders are lost in the reproduction. I find that this peculiarity about a flash has been photographed before, but apparently not noticed. If the reader will refer to an old number of *Knowledge* (vol. xviii. p. 224), he will find a reproduction of a lightning flash taken by Mr. George Primavesi at Tooting. This flash is far more intense than that on my negative, and the dark borders are more developed. The main stream is devoid of ramifications: the exposure lasted for only one second.

To sum up, then, the different appearances of the lightning flashes recorded in these photographs, and others of which I possess either photographs or reproductions; we have the following various kinds:—

| Main stream. | Ramifications. | Reversal down centre. | Source of information. |
|---|---|---|---|
| Bright | None | | Fig. 1, A |
| ,, | Bright | | Fig. 4, B |
| ,, | Dark | | NATURE, vol. lx. p. 423 |
| ,, | None | Dark | *Strand Magazine*, Jan. 1897, p. 41 |
| ,, | Bright | Dark | ? |
| ,, | Dark | Dark | ? |
| Dark | None | | Fig. 3, A |
| ,, | Dark | | Fig. 2, A |
| ,, | Bright | | ? |
| ,, | None | Bright | ? |
| ,, | Dark | Bright | Fig. 4, A |
| ,, | Bright | Bright | ? |

The peculiar flash marked C in Fig. 4 I have not inserted in the above table, as it is difficult to decide under which category it should be placed.

Now in attempting to explain the cause of dark lightning I employed Mr. Clayden's idea as a working hypothesis, but I can find no reference to any illustrations of the experiments he carried out. Mr. Shelford Bidwell, however (NATURE, vol. xlii. p. 153), describes and illustrates one out of a series of experiments he made, and this shows dark and bright flashes made artificially, but the flashes are simply dark or bright, with no other peculiarities.

Further, in a letter which appeared in a very recent issue of this journal, Mr. F. H. Glew mentions that he also has made several experiments with regard to the Clayden effect. The illustration which accompanies his account of these investigations (the *Photographic Journal*, vol. xxiii. No. 7, p. 179) shows, like Mr. Bidwell's, no more than simple dark and bright flashes. I may here mention that the method described by me further on was not very dissimilar to that employed by Mr. Glew, although I was unaware until quite recently of the publication of his to which reference has just been made.

Now the point most interesting to me was, Could one artificially produce on one plate or film *exact* types of dark and bright flashes as shown in the above illustrations; that is, flashes which are dark with *bright cores* and bright with *dark borders?* No photographs of sparks produced artificially have, so far as I know, displayed any of these peculiarities.

I will simply describe one experiment that I made, with this object in view, in the laboratory of the Solar Physics Observatory, Kensington.

To produce the spark I employed a 10-inch Apps' coil, with a pint jar in circuit, fed by two cells of four volts each, the sparking distance being two inches. The camera was a small 5 × 4 by Herr Winkel of Göttingen, fitted with a Zeiss objective. Although it was made only

FIG. 6.—Showing three series of sparks taken on one plate against a white background. During the passage of the sparks at C, the background was artificially illuminated.

for the use of glass plates, by a simple device Eastman's film could be employed. Films, I may mention, eliminate all chances of halation.

The method of procedure was as follows:—

In a darkened room I first of all made an exposure on a *single* (2-inch) spark against a bright (white cardboard) background. On development this bright flash came out naturally *bright*.

I next inserted a new film and repeated the same experiment, except that I did not remove the film or develop it immediately. Covering up the lens carefully, I moved the poles in a vertical plane so that the next spark should fall on a different part of the film, and made a second exposure on two sparks. Again covering the lens, and moving the poles a little in the same direction, I exposed the film once more to a series of four sparks, *but while I allowed the sparks to pass I illuminated the cardboard background by burning one inch of magnesium ribbon at a distance of two feet.*

It may be mentioned that the poles only appear on the negative in their respective positions when the background is artificially illuminated. Fig 6 shows the results obtained. A is the first spark, B the two sparks after the first movement of the poles, and C the last four flashes when the background was artificially illuminated.

A close examination of the figure shows that, not only do we get types of simple bright flashes, but we obtain dark flashes with bright cores and bright flashes with dark boundaries.

Now A (Fig. 6) is exactly similar in type to the dark flash in Fig. 4, A, while the two bright flashes in C correspond also to the bright flashes in Fig. 6.

The peculiar flash at C (Fig. 4) is an exact counterpart of D in Fig. 5.

This experiment leads me to conclude, therefore, that Mr. Clayden's hypothesis is entirely corroborated, and explains very satisfactorily the types of flashes illustrated in the above reproductions from photographs.

In studying Fig. 4 in the light of these results, we can form a good idea of the order of appearance of the flashes. That marked A was undoubtedly the first to occur (if the plate had been immediately developed, it would have come out bright); then the flash B made its appearance, and, being so intense, illuminated the neighbouring region round A that the image of A on the film was affected chemically. C was probably next in order of occurrence, but, being more distant and therefore fainter, did not have any effect on A or B. C, however, was affected by subsequent flashes, which were not bright enough to illuminate the field to alter the intense bright flash B in any way, but which were capable of adding dark borders to its sides. The above order of appearance is to a great extent corroborated by the apparent distances and intensities of the flashes.

There seems very little doubt now that, by varying the intensities of the sparks and that of the illuminated background, one can produce any combination of bright and dark flashes. A glance again at Fig. 6 will show that the appearance of a flash depends simply on the magnitude and presence or absence of the core. The following table sums up the six chief types of flashes that probably can be obtained: the reader will notice that there is a complete cycle commencing and terminating with a dark flash.

1. Dark flash, no core.
2. ,, ,, small bright core.
3. Dark flash, broad bright core; or, Bright flash, narrow dark borders.
4. Bright flash, *no* dark borders.
5. ,, ,, small dark core. This would represent an ordinary weak reversal.
6. Bright flash, broad dark core; or, Dark flash, narrow bright borders. This would represent an ordinary strong reversal.
7. Dark flash, *no* bright borders; or, same as No. 1 above.

In the above list photographs have *actually* been obtained of all the types of flashes that came under the headings 1–5. I have examined all my *negatives* to search for the type No. 6, with the result that I have not found a representation of this kind of flash.

It may be remarked that the types 1–3 are produced as a direct consequence of the Clayden effect, and should therefore only appear on plates which contain more than one flash. The other types, which depend simply on the intensity of the flash, should be obtained when even only one flash appears on a plate.

We thus see that actual photographs of lightning bear out what we should expect from laboratory experiments, and we must therefore answer in the negative the question asked in the first line of this article.

Dark lightning flashes therefore do not exist in nature, but their appearances on photographs are due to some chemical action which takes place in the gelatine film.

In closing this article I wish to draw attention to the great interest which is attached to this most fascinating subject. Every one who has a camera can help in the elucidation of the several points to be studied, and most probably bring new facts to light. The photography of lightning flashes during the night is an easy subject, for one has simply to turn the camera towards the dark sky, and the lightning does all the exposing itself. Unfortunately it is not every one who is aware of this fact, and I know of two instances of amateurs who exposed plates during the same storm and at the same place where I obtained the above pictures, but they tried to *catch the flashes by using instantaneous shutters*. Whether they obtained any positive results I do not know, but one could make a very fair guess.

If any readers of this article would be willing to exchange interesting unmounted lightning photographs obtained by them for copies of any of the above illustrations from the original negatives, the writer would esteem it a favour. (Address: 16 Penywern Road, South Kensington, S.W.) This request suggests to me that it would be important for the furtherance and development of this subject, if there were some recognised "Central-Stelle" to which copies of all such photographs could be sent. Those studying the subject would not then be so much hampered in searching for references to accounts of original observations and reproductions, if a fairly complete collection of copies from original negatives were made accessible. WILLIAM J. S. LOCKYER.

## NOTES.

PROF. A. GRAY, F.R.S., Professor of Physics in the University College of North Wales, has been appointed to succeed Lord Kelvin in the chair of Natural Philosophy in the University of Glasgow, and will at once commence his new duties.

THE Harveian Oration will be delivered at the Royal College of Physicians, London, on October 18, by Dr. G. Vivian Poore, and the Bradshaw Lecture on November 2, by Dr. A. Foxwell.

MAJOR RONALD ROSS and other members of the Liverpool Malaria Expedition have returned to this country very well satisfied with their labours. On the advice of the expedition the authorities at Sierra Leone decided to use every means to exterminate the malaria-spreading mosquito. Major Ross is of opinion that the white population is not careful enough, and that the houses are badly constructed, and compare unfavourably with the residences of white people in India, which are constructed on plans that give the inhabitants every chance of health, despite the tropical climate. He attaches great importance to this question of the construction and situation of the houses. Dr. Fielding Ould, a member of the expedition, has remained behind to consult with the medical officers on the coast respecting measures to be taken for the extermination of the malarial mosquito in the neighbourhood of the principal towns. During the investigation one member of the expedition, Mr. Austin, suffered from malaria; he became infected through sleeping one night without the protection of mosquito curtains.

DRS. CALMETTE AND SALEMBENI, who were sent out by the Pasteur Institute as a commission to study and combat the plague in Oporto, have returned to Paris more than satisfied, it is said, with the success attending their efforts with the anti-plague serum. Dr. Calmette is of opinion that the Portuguese might easily free themselves from plague if they would rigorously carry out the measures which have been recommended to them, and in particular if they would inoculate all the inhabitants of suspected quarters. This, however, they appear unwilling to do.

ACCORDING to the *Civil and Military Gazette*, Lahore, the Indian Government has under its consideration a somewhat comprehensive scheme for the establishment of research laboratories

in various parts of India, and the appointment of health officers to the charge of them. The present laboratory at Muktesar will, it is understood, be further developed, and the staff increased, the establishment becoming the central research laboratory for India, and health officers will be appointed to the charge of laboratories at Calcutta, Madras, Bombay, Agra and Lahore, the new department of bacteriology being ordinarily manned by officers of the Indian Medical Service.

DR. CARL PETERS has, it is stated by Reuter, left Portuguese territory and crossed into Mashonaland. Part of his expedition has, however, been left in the neighbourhood of the ancient ruins re-discovered by him near the Zambesi. Dr. Peters' intention is reported to be the establishment of a permanent station on the Inyanga Highlands, and to explore from that point the whole of Mashonaland from north to south. The explorer claims to have discovered mica, saltpetre and diamonds in a district practically uninhabited, at an altitude of 8000 feet, and, he believes, easily capable of cultivation. As the rainy season is now setting in Dr. Peters will, after exploring some districts on the Pungwe River, proceed to Beira *en route* for England.

WE regret to have to record the death, at the age of fifty-eight, of Mr. John Donaldson, a partner of the engineering firm of Thornycroft, which took place last week. Mr. Donaldson had much to do with the introduction of fast torpedo boats into the British Navy, and was a great believer in his firm's water-tube boiler. He was a member of the Institution of Civil Engineers, the Institution of Naval Architects and the Institution of Mechanical Engineers.

*Science* announces the death, at the age of eighty-four, of Chief Justice C. P. Daly, who for many years took a deep interest in scientific matters, particularly in the branches of geography and botany. Mr. Daly was for thirty-six years president of the American Geographical Society, and was largely instrumental in founding the Society's extensive library, and in securing the endowment of its new building. He also rendered good service to the Botanical Garden of New York, and was one of its managers.

MONUMENTS in memory of Siemens and Krupp will be unveiled at Charlottenburg on the 19th inst., the occasion being the centenary of the Technical Institute of that town.

IT having been decided by a number of friends and pupils of the late Dr. Friedel to place a bust and enlarged photograph of him in the hall of the Sorbonne, a circular asking for subscriptions has been distributed. The bust will be the work of M. Uitain, who executed that of Schutzenberger, and is estimated to cost 3000 francs. Subscriptions should be sent to M. Chason, at the Laboratory of Organic Chemistry, Faculty of Science, the Sorbonne.

THE highest observatory in Germany is now completed. It is situated on the Schnee Koppe, the highest summit of the Silesian Mountains, at an elevation of 5216 feet. It will be managed as an institution of the Prussian State.

MR. W. D. HUNTER, special agent of the Division of Entomology, Department of Agriculture, has, says *Science*, returned to Washington, after having studied the Turtle Mountain region in North Dakota and Manitoba, supposed to be a permanent breeding-ground of the Rocky Mountain locust. This, it is reported, he found not to be the case, and he thinks that the probable breeding-ground is the Assiniboine River, north and east of Regina, a region that will be investigated next season.

ACCORDING to *Nature Notes*, a circular has just been issued to all Catholic missionaries by the Sacred Congregation of the Propagation of the Faith, urging them to use such opportunities as the locality of their mission work affords for the collection of natural history specimens, to be given to scientific societies and institutions. The intention, it is asserted, is not only to interest and encourage such missionaries as are keen naturalists, but also to remove the reproach so commonly held that the Church does not look with favour upon science, and especially biological science.

THERE being much difference of opinion as to the kind of ration best adapted for soldiers and sailors in tropical climates, a prize of 100 dollars, or a medal of that value, as the successful competitor may select, has, says the New York correspondent of the *Lancet*, been offered by Dr. Louis L. Seaman for the best thesis on the subject, viz. "The Ideal Ration for an Army in the Tropics." The competition is open to all commissioned medical officers of the U.S. army and navy, regular and volunteer. The prize is offered through the "Military Service Institution of the United States." The executive council of that body has decided that all papers should be submitted by March 1, 1900.

THE joint committee of the Glamorgan County Council and Cardiff Corporation invite applications for the post of bacteriologist and lecturer, to work under the direction of the medical officers of health of the borough and county. Full particulars as to the duties and emoluments of the office will be found in our advertisement columns.

THE American Mathematical Society, which was established on its present basis so recently as 1894, appears to be in a flourishing condition. Its membership is now over three hundred, and at its recent summer meeting, held at Columbus, Ohio, simultaneously with that of the American Association, no fewer than twenty-four papers were read.

IN the address delivered at the opening of the winter session of the Jenner Institute of Preventive Medicine, on Monday last, Dr. Macfadyen gave an account of the institute and its work. In the course of his remarks he said the Anti-toxin Department was engaged in preparing various therapeutic serums, notably the anti-diphtheritic serum, as well as in research in this important field of work. The primary object of the institute was research, but facilities were afforded for post-graduate instruction in preventive medicine and bacteriology. The students had come from all parts of the world, and a considerable amount of original work had been done by those trained in the laboratories. Investigations were at present being made at the institute with reference to the possible cure or prevention of typhoid fever, tuberculosis and other diseases. The diagnosis of infectious diseases was constantly being carried out for the main parishes of London, as well as the investigation of questions affecting the public health on behalf of sanitary authorities. The chemical and State medicine laboratories would find much to do in connection with water, sewage, food, poisons, &c. A notable addition had been made to the resources of the institute in the Hansen Laboratory for the study of the practical application of bacteriology to industrial and technical processes, and the most important results might be anticipated in the future from this branch of investigation.

THE New York *Electrical Review* gives particulars of a recently invented electrical and chemical fire-alarm apparatus, which gives its indications when the atmosphere becomes so vitiated with smoke that it will not support the combustion of a gas flame. In the interior of the apparatus a small gas flame constantly warms a thermostatic bar, the electric circuit through the apparatus being normally open as long as the flame holds out to burn. If the air in the apartment in which the apparatus is installed becomes vitiated with smoke, the little

gas flame goes out, and the thermostatic bar, cooling off, closes the circuit and gives the alarm.

At the International Fishery Congress held at Bergen in 1898, and at that held at Dieppe, an effort was made to start the publication of an "International Review of Fisheries and Fish Culture," which should serve to maintain constant relations between specialists of this branch of science working in different countries. Such efforts were, however, unsuccessful so far as a favourable decision of the Congresses being arrived at was concerned. This being so, and the want of such an organ being considered a very real one, the Russian Imperial Society of Fish Culture and Fisheries has undertaken the publication of such a periodical as has been mentioned, to contain articles in German, French and English. The first number, dated August, has just reached us and contains many interesting contributions, among which may be mentioned "A Short Comparison between the Caspian and the Baltic Seas," "Short Notices of the Fisheries of Sweden," "Fish Culture in the United States," "Contributions to the Study of Fishing Apparatus." The following programme will give an idea as to the scope of the new journal, which has made a very creditable beginning:—New facts pertaining to fish- and oyster-culture (statistics, new methods used in fish-culture, inventions, &c.). New facts and data pertaining to fisheries (statistics, fishing news, inventions, new laws, &c.). Professional education of fishermen and of workmen engaged in the manufacture of preserved fish. Novelties in the manufacture of fish products (new patents, new canneries, &c.). Improvements in the fish-trade and in the methods of carrying fish (fish-markets, cold-storage houses, refrigerator-cars; new duties on imported fish). The work of fishery-societies. Review of scientific investigations connected with fisheries. New books on fish-culture and fishing. Personal notes.

IN a recent number of the Paris *Comptes rendus* (vol. cxxix. p. 417), M. L. Teisserenc de Bort contributes some interesting particulars relating to the temperature of the free air and its variations from observations obtained from ninety unmanned balloons, sent up from his observatory at Trappes since April 1898. The observations have been spread over every month; seven of the ascents exceeded 14,000 metres, twenty-four 13,000 metres, and fifty-three attained a height of 9000 metres. The discussion of the observations exhibits the following general results: (1) The temperature at various heights presents during the course of the year important and greater variations than have been admitted from older series of observations made in manned balloons. The temperature of 0° C. is found at very different altitudes, varying from the level of the ground in winter to above 4000 metres in summer. The isotherm of −25° C. is met with about 3000 metres in winter and above 7000 m. in summer; in September it was observed even above 8000 m. The isotherm of −40° C. was several times found as low as 6000 m., and is generally met with about 9000 m. and even higher towards the end of summer. The temperature of −50° C. has never been recorded below 8000 m.; its greatest altitude was at 12,000 m. (2) There appears to be a marked tendency to an annual variation of temperature even up to 10,000 m., the maximum being about the end of the summer, and the minimum near the end of the winter. The observations given in a table appended to the paper do not show such a rapid variability with height as has been generally supposed; it appears, further, to vary with the type of weather.

IN the *Atti dei Lincei* viii. (2) 4, Dr. D. Lo. Monaco and L. Panichi give a second note on the action of quinine on the parasite of malaria. The most remarkable result is the effect of solutions of strengths lying between certain limits in provoking the exit of the parasites from the red corpuscles, when the parasites are in the second or adult stage. The authors now find that the action of quinine on the endoglobular parasites of spring fever may be thus summed up: (1) in very dilute solutions it excites them; (2) in less dilute solutions the excitement, which reaches its maximum phase in the exit of the parasite from the red corpuscle, is preceded by a brief contraction; (3) in strong or concentrated solutions it paralyses them. There is still some doubt as to the dose of quinine which should be administered in order to effect a cure, and this probably varies in different patients; but it appears that the doses commonly adopted must be regarded as excessive, and that the rational dose suited for curing an attack of spring fever is comprised between half a gramme and a gramme of bisulphate of quinine.

THE *Sitzungsberichte der physikalisch medicinischen Societät* (Erlangen) contains abstracts of several experiments on kathodic rays. The first of these, by Prof. E. Wiedemann and A. Wehnelt, is a simple proof that while kathodic rays are deflected by a magnet, the Goldstein rays are not directly influenced by magnetic force. In the second note the same authors deal with the question of the repulsion of converging kathodic rays, and describe experiments showing that the rays emanating from a hollow kathode cut one another, and that this result is not inconsistent with Weber's experiments. The third note deals with the variations in the potential of discharge in the kathodic dark space, and their independence of ultra-violet or Röntgen rays. Prof. E. Wiedemann contributes a further note on the "simple" kathodic rays of Deslandres. M. Arnold discusses the influence of the luminosity of the anti-kathode on the emission of Röntgen rays; and A. Moffatt gives an interesting note showing that the power of Röntgen rays (*i.e.* their energy divided by the time) is greater than is commonly supposed, and may be about 1 to 10 calories per second.

THE Calabro-Messinese earthquake of November 16, 1894, occupies a prominent place among recent Italian shocks. A Government commission was immediately appointed to study it, but, for various reasons, the complete report has not yet been published. Prof. Riccò, however, has contributed a summary of the seismological section to the Royal Accademia dei Lincei (*Rendiconti*, vol. viii. pp. 3-12, 35-45), and has illustrated it by a map showing the isoseismal lines of the principal shocks of 1894 and 1783. The meizoseismal area of the earthquake of 1894 is situated about twenty miles north-east of Reggio, and the isoseismal lines (which depend, however, on observations from only 170 places) are roughly concentric with this area, but they expand towards the north-west, and are rather crowded together towards the south-east. As a general rule, they follow the boundaries of the great crystalline masses. The total disturbed area (included within the isoseismal 2) is about 44,000 square miles. Nearly a thousand houses were completely destroyed, and more than 44,000 were damaged; about a hundred persons were killed, and a thousand wounded. The earthquake was registered by seismographs at seven Italian observatories, and by the horizontal pendulum at Nicolaiew. A puteometer at Catania indicated a sudden rise of 17 mm. in the well-water, followed by a fall of 14 mm., after which the surface returned nearly to its original position. The mean surface-velocity of the larger vibrations in Italy was almost exactly 2 km. per second; but it varied with the distance, for the hodograph (see NATURE, vol. lii. p. 632) is at first convex to the axis of the distance and afterwards concave. Prof. Riccò remarks that the earthquake of 1894 may be regarded as an after-shock of the great earthquake of 1783, its epicentre being displaced slightly to the south-west; but its intensity was much less, for the meizoseismal area (that bounded by the isoseismal 10) is only one-sixth of that of the earthquake of 1783.

THE department of vertebrate palæontology of the American Museum of Natural History reports that in 1898 the second expedition for Dinosaurs was sent out to Wyoming in charge of Dr. J. L. Wortman, with a party of four. Deposits of Dinosaur bones very favourably situated were found. In all some 60,000 pounds of fossils were secured. This splendid collection reached the museum entirely uninjured, and one-third of it has already been worked out. The fore and hind limbs of these monster reptiles will furnish subjects of great interest for the public. The exhibition hall has been enriched by the skeletons of two great Dinosaurs. A second party, under the direction of Dr. W. D. Matthew, was at work in 1898 in the fossil beds of north-western Kansas and south-western Nebraska. The Bad Lands of north-eastern Colorado were also found to be a rich collecting-ground. Skulls and parts of skeletons were secured, filling many important gaps in the Museum collection. Portions of skeletons and skulls of fossil camels were found, among which is included a gigantic one of the size and proportions of the giraffe. The party also acquired a large amount of other material. It is a little surprising to notice that, though the museum is doing so much to promote educational and scientific advancement in New York, the income in 1898 was insufficient to meet current expenses.

THE monograph, "The Later Extinct Floras of the United States," left unfinisbed by the death of Prof. Newberry, is to be completed by Dr. Arthur Hollick.

THE Essex Technical Instruction Committee have issued, through the County Technical Laboratories, Chelmsford, a report, compiled by Mr. T. S. Dymond, of a visit paid to Holland by Essex agriculturists in May and June of the present year. The report is interesting reading, and gives a brief outline of the more prominent features of Dutch farming. A perusal of the pamphlet will supply English agriculturists with a few hints which in some cases might with advantage be acted upon in this country.

THE report of the Connecticut Agricultural Experiment Station for 1898 has just been published, and is full of valuable matter. Several of the reports contained in the volume should be of interest and service, not only to inhabitants of the State of Connecticut, but to many others.

A SERIES of illustrated articles on "Radiography," by Mr. James Quick, is begun in the October number of *Science Gossip*. The same issue also contains the continuation of articles on "British Freshwater Mites" and "Butterflies of the Palæarctic Region," and numerous other contributions of popular science.

THE Royal Technical Institute, Salford, has issued its calendar for the session 1899-1900. The list of classes is a large one, and, judging from the illustrations of laboratories, workshops, &c., given, the institute is equipped in a very efficient manner.

THE additions to the Zoological Society's Gardens during the past week include a Smooth-headed Capuchin (*Cebus monachus*) from South-east Brazil, presented by Mr. M. P. Peeker; a Chopi Starling (*Aphobus chopi*) from Brazil, presented by Mr. W. R. Routledge; two Orange-flanked Parrakeets (*Brotogerys pyrrhopterus*) from Western Ecuador, presented by Mr. W. H. St. Quintin; three Palm Squirrels (*Sciurus palmarum*) from India, presented by Mrs. M. E. Tracy; a Brown Capuchin (*Cebus fatuellus*) from Guiana, a Guinea Baboon (*Cynocephalus sphinx*) from Africa, a Striped Snake (*Tropidonotus ordinatus sirtalis*) from North America, three Common Snakes (*Tropidonotus natrix*), a Four-lined Snake (*Coluber quatuorlineatus*), a Tessellated Snake (*Tropidonotus tessellatus*), a Smooth Snake (*Coronella austriaca*), a Glass Snake (*Ophiosaurus apus*), an Eyed Lizard (*Lacerta ocellata*), six Slowworms (*Anguis fragilis*), European, deposited; two Baillon's Aracaris (*Andigena baillonî*) from Brazil, a White-browed Amazon (*Chrysotis albifrons*) from Honduras, twelve Dwarf Chameleons (*Chamaeleon pumilus*) from South Africa, purchased; a Wapiti Deer (*Cervus canadensis*), an Axis Deer (*Cervus axis*), born in the Gardens.

## OUR ASTRONOMICAL COLUMN.

COMET GIACOBINI (1899 E).—We have received the following elements and ephemeris (calculated by Herr J. Moller) from the Centralstelle at Kiel.

*Elements.*

T = 1899 Aug. 26·707. Berlin Mean Time.

$$\left.\begin{array}{r} \omega = 358^\circ\ 46'\cdot1 \\ \Omega = 273\ \ 26\cdot9 \\ i = 79\ \ 53\cdot5 \end{array}\right\} 1899\cdot0$$

$$\log q = 0\cdot23796$$

HOLMES' COMET (1899 *d*).—M. H. J. Zwiers gives in *Ast. Nach.* (Bd. 150, No. 3595) an extended ephemeris of this comet, in the hope that it may still be observed by any one having the necessary optical power, and thus permit of a more exact determination of this orbit.

THE ROTATION OF THE SUN.—In a publication issued from the Lund Observatory, Herr C. A. Schultz Steinheil gives the results of his complete discussion of Dunér's spectroscopic determinations of the sun's rotation, extending over the period June 3, 1887–May 18, 1889.

Taking Dunér's spectroscopic values for different positions round the limb and the centre, these are reduced to heliographic coordinates by a table of declination corrections supplied to the author by M. Dunér, and so furnish over 600 equations of condition, which when grouped according to latitude are brought down to 22. Solving these by the method of least squares, the final result appears as

$$x = 2\cdot054 \quad \pm 0\cdot0042$$
$$i = +18^\circ\cdot12 \pm 0\cdot25$$
$$\Omega = +28^\circ\cdot00 \pm 0\cdot50$$

This means that the result of the new discussion of Dunér's spectroscopic observations is that the sun rotates so that a point on its equator moves with a uniform velocity of 2·054 kilometres per second round an axis the inclination of which towards the axis of the ecliptic is 18°·12, the longitude of the intersection of the sun's equator with the ecliptic being +28°·00.

The value of the velocity $x = 2\cdot054$ is not the true velocity, but the synodic; we get the true value by adding $2d \sin \omega$, where $d$ is the velocity of the earth in its orbit in kilometres per second, and $\omega$ the semi-diameter of the sun, expressed in angular measures as seen from the earth.

THE POLARIS MULTIPLE STAR.—Prof. W. W. Campbell is reported to have stated in the *New York Times*:—

"The recent observations of Polaris at the Lick Observatory

show that its velocity is variable. It is *approaching* the solar system now (September 12) with a velocity of 8 kilometres per second. This will increase in two days to 14 kilometres, and in the next two days will decrease to its former value of 8 kilometres. This cycle of changes is repeated every *four* days. . . . The orbit is nearly circular, and is comparable in size with the moon's orbit round the earth.

"This centre of gravity, and therefore the binary system, is approaching the solar system at present with a velocity of 11·5 kilometres per second. A few measures of the velocity of Polaris made here (Lick) in 1896 gave its velocity of approach at the rate of 20 kilometres per second. Part of this change since 1896 could be due to a change in position of the orbit of the binary system, but most of it must have been produced by the attraction of a *third* body on the two bodies comprising the '*four-day*' system."

A CORRESPONDENT to the *Scientific American* (September 16) says that Mr. J. A. Brashear has just completed one of the pair of large astronomical camera doublets for the Observatory of the University of Heidelberg. They are next to the largest so far made, being 16 inches clear aperture and 80 inches focal length. Two of these doublets, each consisting of four lenses, are to be made, and are to be used almost exclusively for the photographic discovery of new asteroids. The reason for using two cameras is to provide a check on the possible inaccuracies inseparable from the use of photographic plates, such as false images, &c. The track of an asteroid with a lens of this focus on an 8 × 10 plate is only about one-twentieth of an inch long for an exposure of three hours. As the curves of the lenses have necessarily to be very deep, the casting of the great discs was found to be very troublesome. The fund for the equipment has been provided by Miss Catherine Bruce, of New York City, who was also the donor of the largest photographic doublet (24-inch aperture), to the Harvard College Observatory at Arequipa.

WE learn from the *Evening Standard* that the expedition sent by the Vienna Academy of Science to India to observe the shower of meteoric Leonids during the night of November 14–15, or the following night, has started from Trieste. The leader of the expedition is Herr Director Weiss, of the Vienna Observatory, who is accompanied by Prof. von Hepperger, of the Gratz University, the astronomers, Dr. Hillebrand, Dr. Prey, Herr Rheder, and Dr. Mache. The Indian Government has promised to give the expedition, which will make its observations near Delhi, every possible assistance.

## *THE FREEDOM OF THE CITY OF MANCHESTER.*

ON Friday, October 6, the City of Manchester conferred her freedom on Enrigueta Augustina Rylands, Robert Dukinfield Darbishire, and Richard Copley Christie.

### MRS. RYLANDS.

Mrs. Rylands presented to the city the library, magnificent in its contents and beautiful in its fabric, which she built in memory of her husband, John Rylands, whose name it bears—John Rylands, who as "a Manchester merchant built up from the lowliest beginnings a business of unparalleled magnitude, and left behind him a name for industry that never hasted nor rested, and a probity that knew no shame."

Principal Fairbairn, in his inaugural address, drew a remarkable parallel between Alexandria, whose library was the richest in the world, and Manchester, "cities, whose princes were merchants and whose merchants princes," and, he added, "everything that raises a great provincial and industrial city to metropolitan rank makes for higher order, sweeter life and purer manners." The opening of this great library calls for national jubilation.

The noble fabric, designed by Mr. Basil Champneys, is in the fourteenth century Gothic style, and is possibly the finest building erected in England in this generation. The building is built entirely of Penrith limestone, the exterior being the dark red Barbary stone, and the interior delicately shaded Shawk stone.

The staircase which leads to the main library is surmounted with a beautiful octagonal lantern surrounded by a carved stone gallery. The library proper is set back ten feet from the line of the building in order to secure a sufficient supply of light, and is built on the collegiate plan in a long aisle ending in an apse, the total length being 148 feet.

The building is vaulted and groined throughout in stone, it is divided into eight bays occupied by bookcases, and contains a gallery in which this arrangement is repeated; two large rooms opening from the apse contain the collection of Bibles, and the maps. The whole building is elaborately finished with statues and carving, and the fittings are all in harmony with the general scheme of decoration.

Two beautiful traceried windows, by Mr. Charles Kempe, form a notable addition to the beauties of the building. The library contains the famous Althorp collection, and Mrs. Rylands' private collection, which contains Wycliffe MSS. and Wynkyn de Wordes; the library has been endowed, and will be kept up to date.

### MR. R. D. DARBISHIRE AND MR. R. C. CHRISTIE.

When Sir Joseph Whitworth lay on his deathbed he attempted to complete a scheme for the utilisation of his property. But he could not explain so vast an idea, and, throwing out his hands, exclaimed "I cannot do it now; I must leave it to you, who know what it means!"

And it was to Lady Whitworth, to Mr. Christie and to Mr. Darbishire that he left his great wealth.

Lady Whitworth has followed her husband; Manchester has created the two remaining co-legatees her honorary citizens in recognition of the admirable way they have carried out their trust.

In connection with this trust, the legatees presented the site of the Manchester Technical School, and contributed largely to the School of Art; made many valuable gifts of money to the Owens College for the engineering laboratory, the museum, the college hospital property, and for general purposes; and presented ten acres of valuable land as an athletic ground for the College; finally presented the Whitworth Hall, now in course of erection at a cost of 50,000*l.* Presented and partially endowed the Whitworth Park and Art Gallery; erected a public library and hall at Openshaw (where Sir J. Whitworth and Co.'s works are situated).

In addition to the great personal labours in the wise and generous application of the Whitworth estate, Mr. Christie rendered invaluable service to the College in the times of storm and stress. Mr. Christie occupied in 1854–5 the united Chairs of History, Political Economy, Law and Jurisprudence. He is president of many learned societies, and chairman of numerous public bodies, charities and trusts; he is president of the Cancer Home and Pavilion, an admirable institution which originated in his generosity.

His chief literary production is the masterly biography of Etienne Dolet, the second edition of which has just been published.

The magnificent new library at the Owens College which bears his name was his personal gift, and was erected at a cost of 21,000*l.*

The total sum which passed through the hands of the Whitworth Trustees was 1,250,000*l.*; of that sum, 250,000*l.* was spent in redeeming promises and obligations, and the legatees themselves are responsible for the distribution of 960,000*l.*

W. T. L.

## *VISIT OF THE INSTITUTION OF ELECTRICAL ENGINEERS TO SWITZERLAND, AUGUST 31 TO SEPTEMBER 8.*

CONSERVATIVE principles are no doubt of considerable service to England, but perhaps least so when applied to the problems of industry. It is a curious and possibly significant fact that as an electrical power England occupies a very insignificant position, and this in spite of the circumstance that the foundations of the industry were to a great extent laid by English engineers. Some years ago a very authoritative statement was made that in so far as ships of war are concerned our best policy is to watch the experiments of foreign nations and to profit by them, rather than make experiments for ourselves; and it is not uncommon to hear similar remarks with regard to the industrial use of electrical appliances. Unhappily we seem to have forgotten the immense advantages which have accrued to us from our pioneering of the railway industry. No doubt in the early days many mistakes were made and much

money was spent in railway experimenting, which foreign countries were afterwards saved; but meanwhile the railway industry had become established in England, and other countries were for many years practically compelled to purchase their railway equipments in England. It seems to the writer of this article that the position formerly occupied by England in railway matters has been taken by America in respect of electric traction, and by Switzerland in regard to the industry of the distribution of electric power. We now certainly profit by American pioneering in electric lighting and tramway work—but we do not get their experience for nothing, for meanwhile their manufacturing industries have become established, and America takes tithe of us when we become her customers. In Switzerland the absence of coal and the presence of an industrious and highly educated population has no doubt co-operated to bring about the wonderful progress which has been made in developing water powers electrically, and in establishing the corresponding industry of the manufacture of electrical appliances. It was on all accounts a happy inspiration for the Institution of Electrical Engineers to visit Switzerland, and for its members to become personally acquainted with the great electrical works of that country; it is only to be regretted that the remainder of the British public did not accompany the members.

Of course we had long understood that the Swiss had done great things electrically, but a visit was necessary to enable us to form an adequate idea of the industrial revolution which has been effected, and whose importance it is impossible to overestimate. It is also impossible to overestimate the kindly hospitality which was extended to the Institution by the great Swiss manufacturing firms, and indeed by the whole electrical fraternity of Switzerland. We were received everywhere with open arms, works were not only thrown open to our inspection, but every effort was made to explain everything that required explanation, and we were made to feel that not only were we guests, but welcome guests. The following brief account is not intended to be a technical description of our visit, for which the electrical journals may be consulted (an excellent account has already appeared in *Engineering*), but is rather in the nature of a record of the writer's general impressions.

*September* 1.—About half the party arrived at Bâle in the morning and spent the afternoon in a visit to the Alioth works at Münchenstein. There is a great similarity between these works and those of Brown, Boveri and Co. at Baden; both are new, both are clean, both are worked for the most part by polyphase motors, both of them make excellently designed machinery, mostly of the alternate current three-phase type, and both of them seemed to have as much work on hand as they could carry out. Though a minor matter, the design of the brush holders for continuous current dynamos at Münchenstein met with some attention; they were very neatly made of aluminium on correct dynamical principles.

*September* 2.—The rest of the party having arrived we went to see the great Power Station at Rheinfelden on the right hand bank of the Rhine. This station has a capacity of twenty turbines of 840 horse power each, the power being supplied by the water of the Rhine with a fall of from three to five metres. To meet variations in the level of the river, the turbines are constructed in a rather peculiar manner, and in fact consist of two turbines on one shaft. The turbine shafts are supported on an oil film, pumped in below a flange; the same high pressure oil being also employed to work the differential governing gear, which it appeared to do very well indeed. However, the load on the dynamos at Rheinfelden is pretty steady, but we found at some other stations that regulation was performed by hand, especially when the power was used for railway or tramway purposes. Some of the power is used for lighting and motors in the villages round about Rheinfelden, and up to a considerable distance away, the three-phase system being employed at a line pressure of 6800 volts. The bulk of the power, however, is used for chemical works on the spot, viz., aluminium, soda and bleach, and carbide, but we were not allowed to see any of these works. The power is a good deal cheaper than at Niagara, and the whole installation gave one the idea that it had "come to stay," the hydraulic works being very solid and the power house roomy and convenient and well kept, though no doubt it had suffered an extra clean up.

The party was entertained at lunch by the directors of the Rheinfelden works; and Herr Rathenau came from Berlin to welcome us, and give us an invitation to visit Berlin next year, an invitation which it is to be hoped the Institution will accept; in any case, Herr Rathenau deserves our best thanks.

In the afternoon we went on by train to the works of Brown, Boveri and Co. at Baden (Switzerland). The works are fairly large, 1300 men and a staff of 170 being employed, and are as much as possible under one roof. Here we saw much the same kind of work that we had seen at the Alioth works, but on a much larger scale. The most interesting exhibit was undoubtedly Mr. C. E. L. Brown himself, who took great pains to ensure our seeing as much as possible in the time at our disposal. The bulk of the work appears to be the construction of three-phase generators and motors of the ordinary type. The large generators were mounted very conveniently with the fixed portion (armature) on trunnions so that it could be turned round for the convenient execution of repairs. The tools were very modern, but there was not nearly so much repeat work being done as the writer at least had expected: nor was there any show of automatic machines. In fact the works were more like an English than an American works, though on a larger scale and newer than any similar works in England.

*September* 4.—The party being now at Zürich, expeditions were made to the Zürich central station, the works of the Oerlikon Company, the gas engine power house of the Zürich-Oerlikon-Seebach tramway, and the works of Messrs. Escher, Wyss and Co.

*The Central Power Station.*—The whole of the water of the river Limmat, which drains the Lake of Zürich, is, or can be, turned through the turbines of the power station, the general construction being very similar to that at Rheinfelden. A good deal of the power is used for pumping water, the excess water being used in high pressure turbines for electric generation.

The Oerlikon works are very like the works at Baden, but are much older, and the generators on the three-phase principle appeared to be chiefly of the inductor type. The design of the three-phase motors appears to depend very much on the size, the small ones having simple short circuited squirrel-cage rotors, while the larger ones have a regular winding, coupled up star fashion, and arranged for the introduction or removal of resistance by pulling or pressing a rod passing up the rotor shaft. We saw a nearly-finished locomotive for the Jungfrau railway, the motors being three-phase and provided with enormous rheostats for varying the speed and absorbing power when the cars run down hill. Who would have thought twenty years ago that the Arago disc contained such potentialities? The steel castings in this works were good throughout.

The works of Escher, Wyss and Co. do not demand any special note in so far as arrangement, &c., is concerned; but the firm seems thoroughly to understand the art of turbine making, as it should do, seeing that most of the turbines in the country appear to have been made at their works. Special pains were taken here to show us everything that was to be seen, and we had an unrivalled opportunity of inspecting the details of turbine construction.

*Dowson Gas Central Station of the Zürich Oerlikon Street Railway at Oerlikon.*—It was rather a surprise to us to find the street railway driven by Dowson Gas in a land reputed to be covered with water powers. The writer must admit to feeling a certain amount of satisfaction at the idea that the water powers were getting exhausted in the neighbourhood of Zürich before British Industry had become a thing of the past. The truth is that there will be no more cheap power for Zürich until some one or other of the numerous schemes for converting valleys into lakes is actually accomplished and very likely not even then. With regard to the Dowson plant itself, there was nothing very striking about it. The engines were not particularly large, but they appeared well made and particularly well water-jacketed. Little or no information could be obtained of interest to Gas Engine people; but economy of coal must be a great consideration when it costs 32 francs per 1000 kilos.

At the Selnau Transformer Station we had an opportunity of seeing how high-tension three-phase currents are used for transmitting power to a sub-station at which continuous current at 500 volts is generated for driving tramway motors. One of the most interesting things about this sub-station was the switches used for turning on the three-phase current, and so starting the continuous current generators to which the three-phase motors are directly coupled. As is, of course, well known, it is in general necessary that resistance should be inserted in the rotor circuit of a three-phase motor in order to enable it to start under any sort of a load. At the Selnau sub-station the switch

board was placed above a kind of stone cellar into which the high pressure leads were conducted, the pressure being 2000 volts. By moving the levers on the switch board the current could be switched on and resistance gradually removed from the star winding in the rotor circuits, so that by the time these had attained their proper speed, all the additional resistance had been cut out. We saw the operation of starting successfully performed.

A number of diagrams had been prepared to illustrate to us the essential characteristics of the apparatus. One of these curves seemed to show that the efficiency of the three-phase motors remained within a very small percentage of the same value, the load increasing from 40 per cent. to its full value, a fact which seems to illustrate the great advantage which may be and is obtained by using these motors on variable loads.

*Visit to Schaffhausen and Neuhausen.*—One is, of course, always pleased to see Schaffhausen on its own account, but there did not seem any particular electrical reason for visiting it. There is the usual central station, power being taken from the Rhine with a fall of from 4 to 5 metres. A little higher up the river there is another similar but older station, the tail race of which is built under the head race of the lower station. One of the turbines was governed by a device which looked about as simple as the machinery employed in cotton spinning, but it seemed to act all the same, though not better than the simpler devices employed by Escher, Wyss and Co. Some of the electric power is used for driving the machinery of a worsted spinning mill and twine works which were visited by several members of the party. Some of the water of the Rhine is deflected, one might almost say stolen, from above the falls at Neuhausen to work a plant most artistically situated just opposite the castle. There is no question but that the appearance of the falls has suffered by the water so deflected, and it is understood that local vested interest in the appearance of the falls is likely to prove too strong for those who desire to utilise their power.

Part of the afternoon was spent in a visit to the works of Messrs. Sulzer Bros. at Winterthur, so well known to engineers as the birthplace of economical engines. We saw several of the engines whose economic performances have secured the admiration of the engineering world. They are of the compound, tandem type, with modified Corliss valve gear, both cylinders being steam jacketed, and heavily lagged with a non-conducting compound. Outside all is a coating of planished steel, which gives the engine a remarkably fine appearance. It appears that there is some evidence that these engines have on occasion developed one I.H.P. on as little as six kilos of steam.

On Wednesday, September 6, a meeting of the Institution of Electrical Engineers was held in the great hall of the Polytechnikum, to hear a paper by Prof. Amsler on the water power at Schaffhausen. Dr. Amsler was not present himself, his paper being read by the secretary, and afterwards discussed indiscriminately by the English and Swiss engineers present. It is not to be inferred from this that they necessarily understood one another; in fact, the writer was rather surprised to find that the linguistic powers of Swiss engineers do not appear to be appreciably greater than those of their English *confrères*.

It is usual to see the Polytechnikum of Zürich held up for our admiration as representing all that is best in technical education. If magnificence of building, opulence in apparatus and luxury of appointment constitutes a successful Polytechnik, then there is no doubt that quite apart from its staff the Zurich institution deserves the position which it apparently commands. The writer cannot help saying that he did not see a single piece of apparatus which he had not seen thousands of times before, that nearly all the apparatus in the Physical Laboratory appeared to him to be clumsy and old-fashioned in design, and that he saw no evidence of anything except an immense amount of what may perhaps be suitably described as second-class teaching of the "fife and drum" order. With regard to the Chemical Laboratory, the appliances were magnificent; but there again, so far as the actual laboratories were concerned, there was not very much of interest, or if there was we did not see it. The basement of the chemical building was taken up by the most magnificent appliances for drawing in fresh air, either through a stream of water in summer time, or over a heated surface in winter, the whole of the air supply of the building being treated in this manner. So far as the writer could judge, the electro technic department appeared to be the most interesting part of the Polytechnikum, and there was no lack of machinery of all kinds of the latest type. It is understood that the Swiss electrical manufactories make great use of the facilities for testing afforded by the electro technic department of the Polytechnikum. It is fair to add that we were rather hurried in our visit; neither the writer nor any one else saw the whole of the departments; and it was the middle of vacation time, when the busiest chemical laboratory looks like a desert.

Thursday, September 7, was practically occupied by a cheap trip to Engelberg, except that it was not particularly cheap. The greater number of the members visited the Stansstad-Engelberg Railway, and for the first time the majority were able to see how a railway may be driven by means of three-phase motors. The starting and stopping of these machines apparently goes on in the smoothest way, and when the cars are running downhill the motors work as generators and pump power back to the generating station, where it is absorbed by resistances. A still better illustration of traction on the three-phase system was afforded by the visit on the last day of the meeting to the Kander power station, near Spiess, and then to the Burgdorf-Thun Railway. In fact, there was a tolerable consensus of opinion that this was the most important day of the tour. The Kander station is not large, but is equipped in the most modern manner by Brown, Boveri and Co. The water of the Kander at Spiezwyler, with an effective head of about 69 metres, is carried in an iron pipe down to the turbine house, where it operates turbines of about 900 horse-power working upon three-phase alternate current generators working at 4000 volts "composed" pressure and 40 cycles per second. This current is partially used for distribution in the neighbourhood; it is partly raised to 16,000 volts, and transmitted to Berne, Burgdorf and Munsingen, where it is re-transformed and used for general purposes. In addition to this, a large part of the power is transmitted at 16,000 volts, and distributed by means of transformer stations along the course of the Burgdorf-Thun Railway at a pressure of 750 volts. Now an electric railway, as everybody knows, takes its power in a very irregular manner, so that the engineers of the Kander station have had to face the difficulty of regulating a load part of which is practically constant and part of which is exceedingly variable. Some, if not all, of the generators are run in parallel, which means that all of them run strictly in synchronism; consequently, if a load varies, the water-supply must be varied to each turbine at the same time and in the same manner. This was being accomplished by the apparently primitive device of having a man on the stop-valve of each turbine. The writer does not feel that he is entitled to pass an opinion on this practice; but on mentioning what he had seen to M. R. Thury, of Geneva, who has had immense experience of hydraulic electric stations, that engineer expressed himself as confident that it is quite possible to regulate even such a variable load as that of the Kander automatically. The writer was informed that there was an accident to the water pipes at the Kander station not very long ago which upset the regulating devices. The pressure at which the current is generated was regulated by two men at the switch board, who constantly varied the exciting current of the exciters of the generators, which was itself furnished by an independent dynamo which was the subject of regulation. In a station of this kind the difficulty of regulation is no doubt affected by the fact that any variation in the water supplied to the turbines necessarily alters the pressure under which the water is delivered. The switch board was a fine complicated affair on a base of white marble, and some of the fittings appeared to be from America.

*Burgdorf-Thun Railway.*—This railway, 40 kilometres long, is not distinguished in any way from an ordinary railway except that it is being worked electrically by power transmitted from the Kander station. The rolling stock consists of ordinary carriages hauled by electric locomotives, each of which carries two asynchronous 300-horse power motors. The motors are connected with the axles through the intermediary of gearing which we were informed can be adjusted to run at either of two speeds, intermediate regulation being obtained by varying the existence of the rotor windings. Immense rheostats are required for motors of this kind, and are carried to a large extent on the top of the locomotive, so that it has a very strange appearance. Two trolley wires are used, the third one being of course the rails, and into this three-wire system current is fed at intervals by fourteen transformer stations. There is nothing of the tramway about this road. It forms part of the permanent railway system of Switzerland, and runs under much the same conditions as if the trains were hauled by steam locomotives.

The average speed is about 18 kilometres per hour with a train of fifty-five tons. Besides the locomotives, automobile carriages equipped up to 240-horse power are provided for the greater part of the passenger traffic, and these trains run at 36 kilometres per hour. Nothing could have been smoother or more satisfactory than the way in which the train (hauled in this case by one locomotive) was stopped and started, and it got up its speed with satisfactory quickness. It may be safely predicted that though this is the first railway of the type (as distinguished from a tramway) it will not be the last, for the transmission of current at 16,000 volts does not demand wires of more than two millimetres diameter for the distances mentioned. No difficulty seems to be experienced in insulation. Ordinary insulators of the double petticoat type without oil are employed, and no special precautions are taken with regard to the posts on which these wires are supported except to inscribe upon them a genial warning as to the fate likely to befall anybody meddling with them.

The railway up the Jungfrau is also a very interesting work, and an excellent day was spent in a visit to it. It goes up to the Rothstock a long way above the Wengern Alp, and there it ends at present in a tunnel. It happened that while some of the party were standing close to the locomotive in the tunnel the line was struck by lightning, the fuses blown in the power station, and the automatic break on the locomotive instantly went into action, though the train was at rest. From the electrical point of view, there was not much to be seen on the Jungfrau Railway, but we had splendid weather, and regarded the trip as a day's holiday.

On the whole we may, perhaps, say that we saw more, but not better, electrical work than can be done in England. We saw that Swiss engineers have the courage of their convictions, and have done more in railway work than most of us had ever dreamed of; and we saw that, as regards the carbide and similar industries, we cannot hope to compete in England till we can get at something cheaper than steam power. On the other hand, English industries in general cannot be regarded as threatened by Swiss enterprise; and Switzerland itself, regarded as a manufacturing country, requires (as Mr. Raworth remarked) to be rolled and to have its lakes filled up.

Richard Threlfall.

## *THE BRITISH ASSOCIATION.*

### SECTION K.

#### BOTANY.

Opening Address by Sir George King, K.C.I.E., LL.D., F.R.S., President of the Section.

*A Sketch of the History of Indian Botany.*

The earliest references in literature to Indian plants are, of course, those which occur in the Sanskrit classics. These are, however, for the most part vague and obscure. The interest which these references have, great as it may be, is not scientific, and they may therefore be omitted from consideration on the present occasion. The Portuguese, who were the first Europeans to appear in India as conquerors and settlers, did practically nothing in the way of describing the plants of their Eastern possessions. And the first contribution to the knowledge of the botany of what is now British India was made by the Dutch in the shape of the "Hortus Malabaricus," which was undertaken at the instance of Van Rheede, Governor of the territory of Malabar, which during the latter half of the seventeenth century had become a possession of Holland. This book, which is in twelve folio volumes and is illustrated by 794 plates, was published at Amsterdam between the years 1686 and 1703, under the editorship of the distinguished botanist Commelyn. Van Rheede was himself only a botanical amateur, but he had a great love of plants and most enlightened ideas as to the value of a correct and scientific knowledge of them. The "Hortus Malabaricus" was based on specimens collected by Brahmins, on drawings of many of the species made by Mathæus, a Carmelite missionary at Cochin, and on descriptions originally drawn up in the vernacular language of Malabar, which were afterwards translated into Portuguese by Corneiro, a Portuguese official in Cochin, and from that language finally done into Latin by Van Douet. The whole of these operations were carried on under the general superintendence of Casearius, a missionary at Cochin. Of this most interesting work the plates are the best part; in fact, some of these are so good that there is no difficulty in identifying them with the species which they are intended to represent. The next important contribution to the botanical literature of Tropical Asia deals rather with the plants of Dutch than of British India. It was the work of George Everhard Rumph (a native of Hanover), a physician and merchant, who for some time was Dutch Consul at Amboina. The materials for this book were collected mainly by Rumphius himself, and the Latin descriptions and the drawings (of which there are over one thousand) were his own work. The book was printed in 1690, but it remained unpublished during the author's lifetime. Rumph died at Amboina in 1706, and his manuscript, after lying for thirty years in the hands of the Dutch East India Company, was rescued from oblivion by Prof. John Burman, of Amsterdam (commonly known as the elder Burman), and was published under the title of "Herbarium Amboinense," in seven folio volumes, between the years 1741 and 1755. The illustrations of this work cover over a thousand species, but they are printed on 696 plates. These illustrations are as much inferior to those of Van Rheede's book as the descriptions are superior to those of the latter The works of Plukenet, published in London between 1696 and 1705, in quarto, contain figures of a number of Indian plants which, although small in size, are generally good portraits, and therefore deserve mention in an enumeration of botanical books connected with British India. An account of the plants of Ceylon, under the name "Thesaurus Zeylanicus," was published in 1737 by John Burman (the elder Burman), and in this work many of the plants which are common to that island and to Peninsular India are described. Burman's book was founded on the collections of Paul Hermann, who spent seven years (from 1670 to 1677) exploring the flora of Ceylon at the expense of the Dutch East India Company. The nomenclature of the five books already mentioned is all uninominal.

Hermann's Cingalese collection fell, however, sixty years after the publication of Burman's account of it, into the hands of Linnæus, and that great systematist published in 1747 an account of such of the species as were adequately represented by specimens, under the title "Flora Zeylanica." This Hermann herbarium, consisting of 600 species, may still be consulted at the British Museum, by the Trustees of which institution it was acquired, along with many of the other treasures possessed by Sir Joseph Banks. Linnæus's "Flora Zeylanica" was followed in 1768 by the "Flora Indica" of Nicholas Burman (the younger Burman)—an inferior production, in which about 1500 species are described. The herbarium on which this "Flora Indica" was founded now forms part of the great Herbarium Delessert at Geneva.

The active study of botany on the binominal system of nomenclature invented by Linnæus was initiated in India itself by Koenig, a pupil of that great reformer and systematist. It will be convenient to divide the subsequent history of botanic science in India into two periods, the first extending from Koenig's arrival in India in 1768, to that of Sir Joseph Hooker's arrival in 1849; and the second from the latter date to the present day.

The pioneer John Gerard Koenig was a native of the Baltic province of Courland. He was a correspondent of Linnæus, whose pupil he had formerly been. Koenig went out to the Danish settlement at Tranquebar (150 miles south of Madras) in 1768, and at once began the study of botany with all the fervour of an enthusiasm which he succeeded in imparting to various correspondents who were then settled near him in Southern India. These friends formed themselves into a society under the name of "The United Brothers," the chief object of their union being the promotion of botanical study. Three of these brothers, viz. Heyne, Klein and Rottler, were missionaries located near Tranquebar. Gradually the circle widened, and before the century closed the enthusiasm for botanic research had spread to the younger Presidency of Bengal, and the number of workers had increased to about twelve, among whom may be mentioned Fleming, Hunter, Anderson, Berry, John, Roxburgh, Buchanan (afterwards Buchanan-Hamilton), and Sir William Jones, so well known as an Oriental scholar. At first it was the custom of this brotherhood merely to exchange specimens, but gradually names began to be given, and specimens, both named and unnamed, began to be sent to botanists of established reputation in Europe. Many plants of Indian origin came thus to be described by Retz, Roth, Schrader, Willdenow, Vahl and

Smith. Rottler was the only member of the band who himself published in Europe descriptions of any of the new species of his own collecting, and these appeared in the "Nova Acta Acad. Nat. Curiosorum" of Berlin. A little later Sonnerat and other botanists of the French settlement at Pondicherry sent large collections of plants to Paris, and these were followed at a considerably later date by the collections of Leschenhault. These French collections were described chiefly by Lamarck and Poiret. Hitherto botanical work in India had been more or less desultory, and it was not until the establishment in 1787 of the Botanic Garden at Calcutta that a recognised centre of botanical activity was established in British India. Robert Kyd, the founder of that Garden, was more of a gardener than a botanist. He was, however, a man of much energy and shrewdness. The East India Company was still in 1787 a trading company, and a large part of their most profitable business was derived from the nutmegs and other spices exported from their settlements in Penang, Malacca, Amboina, Sumatra, and other islands of the Malayan Archipelago. The Company were also in those days the owners of a fine fleet of sailing vessels, and the teak of which these ships were built had to be obtained from sources outside the Company's possessions. The proposal to found a botanic garden near Calcutta was thus recommended to the Governor of the Company's settlements in Bengal on the ground that, by its means, the cultivation of teak and of the Malayan spices might be introduced into a province near one of the Company's chief Indian centres. Kyd, as a Lieutenant-Colonel of the Company's engineers, and as secretary to the Military Board at Calcutta, occupied a position of considerable influence, and his suggestion evidently fell on no unwilling ears; for the Government of Bengal, with the promptitude to accept and to act on good advice in scientific and semi-scientific matters which has characterised them from the day of Kyd until now, lost no time in taking steps to find a site for the proposed garden. Colonel Kyd's official proposal was dated June 1, 1786, and, in a despatch dated August 2, the Calcutta Government recommended Kyd's proposal to the Court of Directors in London. Posts were slow and infrequent in those days, and the Calcutta Government were impatient. They did not wait for a reply from Leadenhall Street, but in the following July they boldly secured the site recommended by Colonel Kyd. This site covered an area of 300 acres, and the whole of it, with the exception of thirty acres which were subsequently given up to Bishop Middleton for an English college, still continues under cultivation as a botanic garden. Kyd died in 1793, and in the same year his place as superintendent of the garden was taken by Dr. William Roxburgh, a young botanical enthusiast, and one of Koenig's "United Brotherhood." Roxburgh had studied botany in Edinburgh, where he was a favourite pupil of Dr. Hope. Desirous of seeing something of foreign countries, he made several voyages to Madras in ships belonging to the Honourable East India Company. In 1776 he accepted an appointment in the Company's medical establishment, and was posted to the town of Madras, where he very soon made the acquaintance of Koenig. Roxburgh was shortly after transferred to a remote district, a good deal to the north of Madras, then named the Northern Circars. The station of Samulcotta, which formed Roxburgh's headquarters during his sojourn in the Circars, stands on the edge of a hilly region possessing a very interesting flora, and this flora he explored with the greatest ardour; and, as part of the result of his labours, an account of some of the most interesting of its plants was published in London, at the East India Company's expense, in three large folio volumes, under the title, "The Plants of the Coast of Coromandel." This was Roxburgh's earliest publication on a large scale. The first part of this book appeared in 1795, and the last not until 1819, *i.e.* five years after the author's death. The increased facilities afforded to Roxburgh after his transfer to a comparatively well-equipped institution like that at Calcutta induced him at once to begin the preparation of descriptions of all the plants indigenous to British India of which he could procure specimens. And so diligently did he work that, when he was finally driven from India by ill-health in 1813, he left complete and ready for publication the manuscripts of his "Flora Indica" and of his "Hortus Bengalensis" (the latter being an enumeration of the plants in cultivation in the Calcutta garden). He also left admirable coloured drawings (mostly of natural size) of 2533 species of plants indigenous to India. Seldom have twenty years yielded so rich a botanical harvest! Dr. Roxburgh was thus the first botanist who attempted to draw up a systematic account of the plants of India, and his book, which is on the Linnæan system, is the basis of all subsequent works on Indian botany; and until the publication of Sir Joseph Hooker's monumental "Flora of British India," it remained the only single book through which a knowledge of Indian plants could be acquired. Roxburgh was immediately succeeded in the Calcutta garden by Dr. Buchanan-Hamilton, a man of many accomplishments, who had travelled from Nepal in the North to Ava and Mysore in the South, accumulating materials for a gazetteer of the Honourable Company's possessions. Dr. Buchanan was a zoologist as well as a botanist. He had published a valuable account of Mysore, Canara and Malabar, and had collected materials for a work on the Fishes of India; besides having accumulated a large herbarium, part of which may now be consulted at the University of Edinburgh. Prior to his death Buchanan-Hamilton had begun to write a learned commentary on Van Rheede's "Hortus Malabaricus." Many of his Nepalese collections were described in 1825 (a few years before his own death) by Don in his "Prodromus Floræ Nepalensis." Buchanan-Hamilton remained only one year at Calcutta, and in 1815 he was succeeded by Nathaniel Wallich, a native of Copenhagen, who, prior to his appointment to the Calcutta garden, had been attached to the Danish settlement at Serampore, twenty miles higher up the Hooghly. Wallich remained superintendent of the Calcutta garden for thirty years. In 1846 he went to England, and in 1854 he died. During his tenure of office in the Calcutta garden, Wallich organised collecting expeditions to the then little-known regions of Kamaon and Nepal (in the Himalaya), to Oudh, Rohilcund, Sylhet, Tenasserim, Penang, and Singapore. He undertook, in fact, a botanical survey of a large part of the Company's possessions in India. The vast materials thus collected under his own immediate direction, and the various contributions made by others, were taken to London by him in 1828. With these were subsequently incorporated the collections of Russell, Klein, Heyne, Rottler, Buchanan-Hamilton, Roxburgh, and Wight. And by the help of a band of distinguished European botanists, among whom may be named De Candolle, Kunth, Lindley, Meissner, Nees von Esenbeck, Von Martius and Bentham (the latter in a very special manner), this vast mass of material was classified and named specifically. A catalogue of the collection was prepared by Wallich himself (largely aided by Bentham), and sets of the named specimens were distributed to the leading botanical institutions in Europe, every example of each species bearing the same number. No description of the whole collection was ever attempted, but many of the plants belonging to it were subsequently described in various places and at various times. So extensive was the Wallichian distribution that, amongst the names and synonyms of tropical Asiatic plants, no citation is more frequent in botanical books than that of the contraction "Wall. Cat." Besides the naming and distribution of this gigantic collection, Wallich prepared and published, at the expense of the same liberal and enlightened East India Company, his "Plantæ Asiaticæ Rariores," in three folio volumes with 300 coloured plates. He also contributed to an edition of Roxburgh's "Flora Indica," which was begun by the celebrated Dr. Carey of Serampore, descriptions of many plants of his own collecting. But the task of publishing his discoveries in this way proved beyond his powers, as it would have proved beyond those of any one who had only 365 days to his year, and less than a hundred years as his term of life! Carey and Wallich's edition of Roxburgh's "Flora Indica" was brought to an untimely conclusion at the end of the *Pentandria Monogynia* of Linnæus. Wallich also began an illustrated account of the flora of Nepal under the title, "Tentamen Floræ Nepalensis." But this also came to a premature end with the publication of its second part.

During much of the time that Wallich was labouring in Northern India, Robert Wight, a botanist of remarkable sagacity and of boundless energy, was labouring in Southern India, chiefly in parts of the Peninsula different from those in which Koenig and his band had worked. Wight was never liberally supported by the Government of Madras, and it was mostly by his own efforts and from his own resources that his collections were made and that his botanical works were published. The chief of the latter is his "Icones Plantarum." This book consists of figures with descriptions of more than two thousand Indian species. A good many of the plates are indeed copies

from the suite of drawings already referred to as having been made at Calcutta by Dr. Roxburgh. The rest are from drawings made, either by native artists under his personal supervision, or by his own hands. Ample evidence of the extraordinary energy of Dr. Wight is afforded by the facts that, although he had to teach the native artists whom he employed both to draw and to lithograph, the two thousand *Icones* which he published and described were issued during the short period of thirteen years, and that during the whole of this time he performed his official duties as a medical officer.

Besides this *magnum opus*, Wight published his *Spicilegium Nilghirense* in two vols. quarto, with 200 coloured plates. And between 1840 and 1850 he issued in two vols. quarto, with 200 plates, another book named "Illustrations of Indian Botany," the object of which was to give figures and fuller descriptions of some of the chief species described in a systematic book of the highest botanical merit, which he prepared conjointly with Dr. J. Walker-Arnot, Professor of Botany in the University of Glasgow, and which was published under the title "Prodromus Floræ Peninsulæ Indicæ." The "Prodromus" was the first attempt at a flora of any part of India in which the natural system of classification was followed. Owing chiefly to the death of Dr. Walker-Arnot, this work was never completed, and this splendid fragment of a flora of Peninsular India ends with the natural order *Dipsaceae*.

The next great Indian botanist whose labours demand our attention is William Griffith. Born in 1810, sixteen years after Wight, and twenty-four years later than Wallich, Griffith died before either. But the labours even of such devotees to science as were these two are quite eclipsed by those of this most remarkable man. Griffith's botanical career in India was begun in Tenasserim. From thence he made botanical expeditions to the Assam valley, exploring the Mishmi, Khasia and Naga ranges. From the latter he passed by a route never since traversed by a botanist, through the Hookung valley down the Irrawadi to Rangoon. Having been appointed, soon after his arrival in Rangoon, surgeon to the Embassy to Bhotan, he explored part of that country and also part of the neighbouring one of Sikkim. At the conclusion of this exploration he was transferred to the opposite extremity of the Northern frontier, and was posted to the Army of the Indus. After the subjugation of Cabul, he penetrated to Khorassan. Subsequently he visited the portion of the Himalaya of which Simla is now the best-known spot. He then made a run down the Nerbudda valley in Central India, and finally appeared in Malacca as Civil Surgeon of that Settlement. At the latter place he soon died of an abscess of the liver brought on by the hardships he had undergone on his various travels, which were made under conditions most inimical to health, in countries then absolutely unvisited by Europeans. No botanist ever made such extensive explorations, nor himself collected so many species (9000) as Griffith did during the brief thirteen years of his Indian career; none ever made so many field notes or wrote so many descriptions of plants from living specimens. His botanical predecessors and contemporaries were men of ability and devotion. Griffith was a man of genius. He did not confine himself to the study of flowering plants, nor to the study of them from the point of view of their place in any system of classification. He also studied their morphology. The difficult problems in the latter naturally had most attraction for him, and we find him publishing, in the *Linnaean Transactions*, the results of his researches on the ovule in *Santalum*, *Loranthus*, *Viscum*, and *Cycas*. Griffith was also a cryptogamist. He collected, studied, and wrote much on Mosses, Liverworts, *Marsiliaceae*, and Lycopods, and he made hundreds of drawings to illustrate his microscopic observations. Wherever he travelled he made sketches of the most striking features in the scenery. His habit of making notes was inveterate; and his itinerary diaries are full of information, not only on the botany, but also on the zoology, physical geography, geology, meteorology, archæology and agriculture of the countries through which he passed. His manuscripts and drawings, although left in rather a chaotic state, were published after his death under the editorship of Dr. McClelland, at the expense of the enlightened and ever-liberal East India Company. They occupy six volumes in octavo, four in quarto, and one (a "Monograph of Palms") in folio.

Another botanist of much fame, who died prematurely in 1822, after an Indian career of only nine years, was William Jack. In 1814-15, Jack accompanied Ochterlony's army to the Nepal terai. He was transferred in 1818 to the Company's settlement in Sumatra under Sir Stamford Raffles, and during the four years of his residence in Sumatra he contributed to botanical literature descriptions of many new genera and species which were published in his "Malayan Miscellanies." His collections, unfortunately, were for the most part lost by an accident, but those which were saved are now in the Herbarium Delessert in Geneva.

Somewhat similar to Griffith in temperament and versatility was the brilliant Victor Jacquemont, a French botanist who, at the instance of the Paris Natural History Museum, travelled in India for three years from 1829 to 1832. During this period Jacquemont collected largely in the Gangetic plain. He then entered the North-west Himalaya at Mussourie, explored Gharwal and Sirmur, ascended the Sutlej to Kanawer and Piti (at that time unexplored), visited Cashmir, and returning to the plains, crossed Northern Rajputana to Malwa and the Deccan. He finally reached Bombay with the intention of returning to France. But at Bombay he succumbed to disease of the liver, brought on by hard work and exposure. His remains, after having lain in the cemetery there for fifty years, were, with that tender regard for the personality of her famous sons which France has always shown, exhumed in 1881, and conveyed in a French frigate to find a permanent resting-place in the place of Jacquemont's birth. Jacquemont's collections were transmitted to Paris, and his plants were described by Cambessedes and Decaisne, while his non-botanical collections were elaborated by workers in the branches of science to which they respectively appertained, the whole being published in four volumes quarto, at the expense of the French Government.

The roll of eminent botanists who worked in India during the first half of the century closes with the name of Thomas Thomson, who collected plants extensively between 1842 and 1847 in Rohilkund and the Punjab, and again still more extensively during a Government mission to the North-west Himalaya and Tibet which was continued from 1847 to 1849. During this period Dr. Thomson explored Simla, Kanawar, Piti, Cashmir, Ladak, and part of the Karakoram. His collections, which were large and important, were transmitted to the Botanic Garden at Calcutta, and thence in part to Kew. They formed no insignificant part of the materials on which the "Flora Indica" and "Flora of British India" were founded. Dr. Thomson also published an account of his travels—an admirable book, though now jostled out of memory by the quantities of subsequently issued books of Himalayan travel and adventure.

About the year 1820 a second centre of botanical enterprise was established at Seharunpore, in the North-west Provinces. A large old garden near that important town, which had been originally founded by some Mahommedan nobles of the Delhi Court, was taken over by the Honourable Company, and was gradually put upon a scientific basis by Dr. George Govan, who was appointed its first superintendent. Dr. Govan was in 1823 succeeded by Dr. J. Forbes Royle, and he in 1832 by Dr. Hugh Falconer. Dr. Royle made collections in the Jumno-Gangetic plain, in the Lower Gharwal Himalaya, and in Cashmir. He was distinguished in the field of economic rather than in that of systematic botany, his chief contribution to the latter having been a folio volume entitled "Illustrations of the Botany of the Himalaya Mountains." His valuable labours as an economic botanist will be noticed later on. Hugh Falconer was an accomplished palæontologist who devoted but little of his splendid talents to botany. His great contribution to palæontology, the value of which it is almost impossible to over-estimate, consisted of his exploration and classification of the tertiary fossils of the Sewalik range. Falconer was transferred to the Calcutta Garden in 1842. He was succeeded at Seharunpore by Dr. W. Jameson, who explored the botany of Gharwal, Kamaon and Cashmir, but who published nothing botanical, his chief energies having been devoted to the useful work of introducing the cultivation of the China tea plant into British India, and this he did (as will afterwards be mentioned) with triumphant success.

During the first half of the century a considerable amount of excellent botanic work was done in Western India by Graham, Law, Nimmo, Gibson, Stocks and Dalzell, the results of whose labours culminated in the preparation by Graham of a list of the plants of Bombay, which was not, however, published until 1839 (after his death); in the publication by Stocks of various papers on the botany of Scinde; and in the publi-

cation by Dalzell in 1861 of his "Flora of Bombay." It is impossible in a brief review like the present to mention the names of all the workers who, in various parts of the gradually extending Indian Empire, added to our knowledge of its botanical wealth. It must suffice to mention the names of a few of the chief, such as Hardwicke, Madden, Munro, Edgeworth, Lance and Vicary, who collected and observed in Northern India, and who all, except the two last mentioned, also published botanical papers and pamphlets of more or less importance; Jenkins, Masters, Mack, Simons and Oldham, who all collected extensively in Assam; Hofmeister, who accompanied Prince Waldemar of Prussia, and whose collections form the basis of the fine work by Klotsch and Garcke (*Reis. Pr. Wald.*); Norris, Prince, Lobb and Cuming, whose labours were in Penang and Malacca; and last, but not least, Strachey and Winterbottom, whose large and valuable collections, amounting to about 2000 species, were made during 1848 to 1850 in the higher ranges of the Kamaon and Gharwal Himalaya, and in the adjacent parts of Tibet. In referring to the latter classic Herbarium, Sir Joseph Hooker remarks that it is "the most valuable for its size that has ever been distributed from India." General Strachey is the only one who survives of the splendid band of collectors whom I have mentioned. I cannot conclude this brief account of the botanical labours of our first period without mentioning one more book, and that is the "Hortus Calcuttensis" of Voigt. Under the form of a list, this excellent work, published in 1845, contains a great deal of information about the plants growing near Calcutta, either wild or in fields and gardens. It is strong in vernacular names and vegetable economics.

(*To be continued.*)

## *MATHEMATICS AT THE BRITISH ASSOCIATION.*

THE visit of the French Association to Dover necessitated some departures from the usual programme of the British Association week, and the mathematical meeting was held this year on Monday, September 18. Prof. Forsyth, of Cambridge, presided over a well-filled room.

The session opened with the formal communication of two reports of committees: the first, drawn up by Prof. Karl Pearson, and practically forming a continuation of a previous report, contains a set of tables of certain functions connected with the integral

$$G(r, \nu) = \int_0^\pi \sin^r\theta e^{\nu\theta} d\theta,$$

for integral values of $r$ from 1 to 50, and for values of $\nu$ at certain intervals from 0 to 1. These functions are of importance in certain statistical problems.

The second report consists substantially of the new "Canon Arithmeticus" which Lieut.-Colonel Cunningham has prepared; the Association has made a grant for publishing the tables as a separate volume (they cannot well be fitted into the comparatively small page of the B.A. Report), and it is to be hoped that before long they will become generally available for workers in the Theory of Numbers.

The first of the papers was read by Dr. Francis Galton, on "The Median Estimate." Dr. Galton proposes to substitute a scientific method for the very unsatisfactory ways in which the collective opinion of committees and assemblies of various kinds is ascertained, in respect to the most suitable amount of money to be granted for any particular purpose. How is that medium amount to be ascertained which is the fairest compromise between many different opinions? An average value—*i.e.* the arithmetic mean of the different estimates—may greatly mislead, because a single voter is able to produce an effect far beyond his due share by writing down an unreasonably large or unreasonably small sum. Again, few persons know what they want with sufficient clearness to enable them to express it in numerical terms, from which alone an average may be derived; much deeper thought-searching is needed to enable a man to make such a precise affirmation as that "in my opinion the bonus to be given should be 80*l*.," than to enable him to say "I do not think he deserves so much as 100*l*., certainly not more than 100*l*."

Dr. Galton's plan for discovering the medium of the various sums desired by the several voters is to specify any two reasonable amounts A and B, and to find what percentage $a$ of voters think that the sum ought to be less than A, and what percentage $b$ vote for less than B. It may now be assumed that the estimates will be distributed on either side of their (unknown) *median* $m$, with an (unknown) quartile $q$, in approximate accordance with the normal law of frequency of error; and thus (using the table of centiles given in the author's "Natural Inheritance") the required median value can be found.

This was followed by a paper "On a system of invariants for parallel configurations in space," by Prof. Forsyth. The process followed by the author is one in which English mathematicians have always excelled—namely, the deduction of difficult analytical results from simple geometrical considerations. Prof. Forsyth's final formulæ may be regarded as invariantive relations between certain definite integrals: the way in which he finds them is as follows:—

Consider any plane curve; if we suppose a circle of constant size to roll on the curve, its envelope will be another curve, which is said to be *parallel* to the original one. If now L be the length and A the area of a curve, it is found that the quantity $A - \frac{1}{4\pi}L^2$ has the same value for the parallel as for the original curve; in other words,

$$A - \frac{1}{4\pi}L^2$$

is *invariantive* for parallel curves. Similarly in space of three dimensions, the envelope of a sphere of fixed size which rolls on a given surface is another *parallel* surface; and if V be the volume contained by a surface, S its superficial area, and L twice the surface-aggregate of the mean of the curvatures at any point, then it is found that the quantities

$$S - \frac{1}{16\pi}L^2 \text{ and } V - \frac{1}{8\pi}LS + \frac{1}{192\pi^2}L^3$$

are invariantive for all parallel surfaces.

Similar results hold for space of $n$ dimensions. At the end of the paper the expressions obtained are shown to be connected with the ordinary invariant-theory of binary forms.

The next paper, read by Prof. Everett, was concerned with "The Notation of the Calculus of Differences." In conjunction with the ordinary symbol $\Delta$, defined by

$$\Delta y_n = y_{n+1} - y_n,$$

Prof. Everett employs another symbol $\delta$, defined by

$$\delta y_n = y_n - y_{n-1},$$

so that

$$\delta = \Delta/_{1+}\Delta.$$

The use of $\delta$ simplifies some of the well-known formulæ of the calculus of finite differences.

Prof. A. C. Dixon, of Galway, followed, with a paper "On the Partial Differential Equation of the Second Order." Let $z$ be the dependent, and $x$ and $y$ the independent, variables; and with the usual notation, let

$$p = \frac{\partial z}{\partial x}, \quad q = \frac{\partial z}{\partial y}, \quad r = \frac{\partial z^2}{\partial x^2}, \quad s = \frac{\partial z^2}{\partial x \partial y}, \quad t = \frac{\partial z^2}{\partial y^2},$$

and consider the differential equation

$$f(x, y, z, p, q, r, s, t) = 0.$$

This may be supposed solved by using two more relations

$$u = a, \quad v = b,$$

among the quantities $x, y, z, p, q, r, s, t$, to give values of $r, s, t$, which, when substituted in

$$dz = pdx + qdy, \quad dp = rdx + sdy, \quad dq = sdx + tdy,$$

render these three equations integrable. This will not be possible, of course, unless the expressions $u$, $v$, fulfil certain conditions. Prof. Dixon considers the case in which $u$ can be so determined that $v$ is only subjected to one condition, and finds that then $du$ is a linear combination of the differential expressions used in Hamburger's method of solution. If such a function $u$ can be found, the system $f=0$, $u=a$, will have a series of solutions depending on an arbitrary function of one variable, and involving two further arbitrary constants.

The next paper, "On the Fundamental Differential Equations of Geometry," was read by Dr. Irving Stringham, of the University of California. Dr. Stringham derives the analytical formulæ for non-Euclidian Geometry by following a procedure indicated by Feye St. Marie, and later discussed in Killing's "Nicht-Euclidischen Raumformen." Within an infinitesimal domain in non-Euclidian space, the propositions of Euclidian

Geometry may be regarded as true; from this fact can be deduced a group of equations typified by

$$\frac{da}{d\alpha}=\frac{f(b)}{\sin\gamma},\quad \frac{db}{aa}=\cos\gamma,\quad f'(b)=-\frac{d\gamma}{d\alpha},$$

where $a$, $b$, $c$, are the sides of a triangle, and $\alpha$, $\beta$, $\gamma$, the corresponding angles. From these, by appropriate eliminations and transformations, the differential equation

$$\{f(a)\}^2=-\kappa^2[1-\{f'(a)\}^2]$$

can be found for the function $f$. Solving this, we have

$$f(a)=\kappa\sinh\frac{a}{\kappa},$$

and thence can derive the fundamental equations of non-Euclidian measurement.

$$\sinh\frac{a}{\kappa}\Big/\sinh\alpha=\sinh\frac{b}{\kappa}\Big/\sin\beta=\sinh\frac{c}{\kappa}\Big/\sin\gamma.$$

This was followed by the communication of a Report on the Problem of Three Bodies, which Mr. E. T. Whittaker was commissioned to prepare at the Toronto meeting. In a general sketch of the results, Mr. Whittaker explained the transformation which has taken place in dynamical astronomy as a result of the researches of Newcomb, Hill, Lindstedt and Poincaré. Formerly the subject might be said to consist of two departments—the planetary and lunar theories; now the distinction between these was becoming less prominent, as the Problem of Three Bodies was treated in greater generality. Among the advances referred to were Dr. Hill's introduction of periodic orbits as a substitute for Keplerian ellipses in the first approximation to the solution, Newcomb's proof that the problem can be solved by series in which the time occurs only in the arguments of trigonometric functions, Poincaré's theorem that these series are only asymptotic expansions, and Bruns' result that the system possesses no algebraic integrals other than those already known.

A second paper by Prof. Forsyth, "On Singular Solutions of Ordinary Differential Equations," described some properties of the $p$-discriminant and $c$-discriminant of an ordinary differential equation of the first order. The two last papers on the list were "An Application and Interpretation of Infinitesimal Transformations," by Dr. E. O. Lovett, of Princeton University, N.J.; and "On Fermat's Numbers," by Lieut.-Colonel Cunningham. In the absence of their authors the papers were communicated by title, and the session was closed.

Looking at the papers as a whole, they were of just that character which makes the B.A. meeting useful to mathematicians; that is, they related not so much to abstruse continuations of well-known theories as to new and little-known subjects, suggestions of improved notations, reports on the recent progress of different branches of mathematics, and generally all those topics for which discussion at a real meeting is more important than the publication of a paper.

## PHYSICS AT THE BRITISH ASSOCIATION.

THE attendance of physicists at Dover was rather smaller than usual, on account of the occurrence of the Volta Centenary celebrations at Como and the simultaneous meetings of the French Association for the Advancement of Science at Boulogne. Several of those who in past years have been leaders in the discussions of Section A were this year conspicuous by their absence. Nevertheless, the papers read maintained a high standard of excellence, and the reports presented indicate that good work is being done by the committees appointed for scientific research.

The address delivered by Prof. Poynting, as President of the Section, was the subject of many conversations, not only among physicists but with biologists also; the existence of the sharp line which he indicated between the psychical and physical methods and the phenomena to which each is applicable, was acknowledged on all sides. The physicists were divided on the question of the danger of too much hypothesis, and especially on the possibility of the propagation of electromagnetic waves in air being due to the air as much as to the ether. All, however, were agreed in the expression of thanks to the President, proposed by Sir George Stokes and seconded by Sir Norman Lockyer.

In a paper on the spectroscopic examination of contrast phenomena, Mr. G. J. Burch described experiments which lend great support to the Young-Helmholtz theory of colour-vision. If the eye is fatigued by exposure to a very intense red light, such as sunlight filtered through red screens and focussed on the eye, and a spectrum be then looked at, the red is invisible; but the rest of the spectrum, green to violet, appears in its ordinary colours. Red-blindness is therefore not accompanied by green-blindness, as Hering's theory requires. Further experiments on the blue and violet portions of the spectrum have led Mr. Burch to the conclusion that we have separate primary sensations for blue and violet, in addition to those for red and green, making four altogether instead of the three postulated by the Young-Helmholtz theory. The experiments are the more convincing because carried out with spectral colours, thus avoiding all errors due to the impurity of pigment colours. In the discussion on the paper several members took part; Sir George Stokes said experiments led him to believe that lobelia blue is a primary sensation, and Principal Glazebrook suggested that the theory should be tested by colour-matches on a spectrophotometer.

Prof. Callendar gave the preliminary results of a research on the variation of the specific heat of water with temperature, which he commenced in Montreal with Mr. H. T. Barnes, and which is now being continued by the latter. The method of experiment consists in allowing water to flow steadily through a narrow tube along which a platinum wire runs axially; on passing a constant electric current through the wire the water finally acquires a steady temperature-difference between the inlet and outlet of the tube, which is measured by platinum thermometers and automatically recorded. Radiation corrections are reduced to a minimum by surrounding the tube with a vacuum-jacket, and the electrical energy supplied is measured by observing the current and the potential-difference between the ends of the wire in the tube. The results show that the specific heat of water has a minimum value of 0·995 in the neighbourhood of 40° C., it rises to 1·000 as the temperature falls to 10° C., and continues to rise rapidly as the temperature decreases. On increasing the temperature above 40° C. the specific heat rises to 0·997 at 60° C. Further experiments will be made in the neighbourhood of the freezing point and on either side of it.

The committee on electrolysis and electro-chemistry has undertaken the comparison of the variation of electrical conductivity with concentration, and the variation of freezing point with concentration for identical very dilute aqueous solutions of electrolytes. The electrical measurements have been successfully carried out by Mr. W. C. Whetham, but the freezing point determinations, undertaken by Mr. E. H. Griffiths, have been delayed by the discovery of errors arising from the presence of dissolved gases in the solutions. Incidentally Mr. Griffiths remarked that he was able to measure temperatures to within three or four parts in a million.

Dr. R. A. Lehfeldt, at a subsequent meeting, called attention to a flaw in Nernst's theory of electrolytic solution pressure. According to this theory, when a metal is immersed in an electrolyte ions are torn either from the metal or from the solution according as the solution-pressure is greater or less than the osmotic pressure of the ions in solution. It is usually supposed that the mass of the ions deposited or dissolved is so extremely small that it cannot be detected; the author showed, however, by considering the electrostatic tension due to the ionic charges, that the amount dissolved should be easily weighable, at any rate in the case of zinc.

The stability of an ether containing long, thin, empty vortex filaments was discussed in a communication by Prof. FitzGerald on the energy per cubic centimetre in a turbulent liquid transmitting laminar waves. Lord Kelvin considered this subject in 1887, and concluded that rapid diffusion would make the structure unstable. The author held the opinion (though possibly Lord Kelvin would differ from him) that the turbulency of a sufficiently fine-grained irregularly turbulent liquid would ultimately diffuse so slowly that Lord Kelvin's investigation could be applied to it.

Until the meeting of the Association in 1893, it was generally supposed that the absence of an atmosphere from the moon, and of hydrogen from our own atmosphere, is due to the high average velocity of the gaseous molecules, which is sufficient to carry them beyond the range of the moon's or earth's attraction. On that occasion Prof. Bryan demonstrated the incorrectness of this view for the case of the moon, and he has since extended his calculations to the cases of hydrogen and helium in the

earth's atmosphere, and of water vapour in the atmosphere of Mars. The method of calculation is to determine the number of years which would be required for the planet to lose from its surface a layer of the gas one centimetre thick at various temperatures. The results show that the earth might retain helium, but would lose hydrogen appreciably at ordinary temperatures, and that Mars might retain water vapour at ordinary temperatures. If helium ever existed on the earth's surface, it must have escaped when the surface was much hotter than at present, whereas a smaller elevation of temperature would cause water vapour to escape from the surface of Mars.

Prof. W. F. Barrett described the thermo-electric properties of an alloy containing iron 68·8 per cent., nickel 25·0, manganese 5·0, and carbon 1·2. When a thermo-electric couple is formed of this metal and iron, the electromotive force rises with temperature to 300° C.; it then remains steady until 500° C. is reached, after which it falls slightly and rises again to 1100° C.; the fluctuations of electromotive force do not exceed 4 per cent. of the total value. When the alloy forms a couple with nickel the results are similar, but the range of variation is slightly greater.

The committee on the heat of combination of metals in the formation of alloys, appointed last year to assist Dr. A. Galt in his experiments on this subject, reported the completion of their work. Only alloys of zinc and copper have been examined, twenty-two in number and containing from 5 to 90 per cent. of copper; the difference between the amounts of heat evolved by dissolving in nitric acid unit mass of the alloy and corresponding amounts of the mixed metals was taken as the heat of combination of the metals. The results indicate a negative heat of combination for alloys rich in zinc, the numerical value of which is a maximum when the alloy contains 16 per cent. of copper. The formation of an alloy containing about 24 per cent. of copper takes places without absorption or evolution of heat, while for 38 per cent. of copper the heat of combination is a maximum and positive; beyond this it diminishes to zero for pure copper. In the absence of Dr. Galt and other members of the committee no reply was given to a serious criticism by Prof. Vernon Harcourt, that in the experiments no account was apparently taken of the fact that the products arising from the solution of an alloy in nitric acid are not the same as would be obtained from the mixed metals. In his paper read last year at Bristol, Dr. Galt mentioned that he had made many preliminary experiments, and possibly he has examined this point; if not, the results obtained by the committee will be somewhat vitiated.

A preliminary report of the committee on radiation from a source of light in a magnetic field was communicated to the Section, the chief points in which were (1) the discovery that light passing through a magnetic field at right angles to the lines of force suffers absorption (see NATURE, vol. lix. pp. 228–9, January 5, 1899); (2) the various modified forms of triplet are true magnetic perturbations of the same kind as the normal triplet; (3) the spectral lines of a substance may be divided into groups such that all members of one group suffer the same kind of perturbation (see NATURE, vol. lix. p. 248, January 12, 1899).

The Zeeman effect is attributed to the action of a magnetic field on the moving ions; recently Mr. C. E. S. Phillips has discovered an apparently cognate phenomenon, which he described in his paper on the production in rarefied gases of luminous rings in rotation about lines of magnetic force. An electric discharge is passed between soft iron electrodes in a Crookes' vacuum tube; on stopping the discharge and setting up a magnetic field between the electrodes, a luminous ring forms with its plane at right angles to the lines of force and in rotation about the magnetic axis. The direction of rotation is that which would be communicated to negatively charged particles, and is reversed on reversing the magnetic field; the luminosity persists sometimes for a minute, and reversal of the magnetic field causes it to brighten momentarily. Two explanations of the phenomenon have been given; one is that the rotating matter consists of ions or electrons, and the other that the matter consists of gas particles which have acquired a negative charge by contact with the walls of the tube. From experiments of Prof. J. J. Thomson, it appears that negative ions move more quickly than positive, which would account for the greater luminosity of the negative ions when set in rotation.

In a note on deep-sea waves, Mr. V. Cornish endeavoured to trace relations between the amplitude, wave-length, and wind-velocity for waves on the surface of deep water. Sir George Stokes pointed out that the amplitude observed is not that of a simple wave, but is the resultant effect of a train of waves of different periods and lengths.

At the meeting of the Section on Saturday the visitors from the French Association at Boulogne were present, and the President extended to them a hearty welcome, which was acknowledged by M. Benoit, as president of the Physical Section of the French Association. A paper was then communicated by Prof. J. J. Thomson, on the existence of masses smaller than the atoms. He stated that several lines of research lead to a determination of the ratio of the mass of an atom ($m$) to the charge carried by the atom ($e$). Among these are electrolysis, the velocity of charged particles in a magnetic field, and the magnetic deflexion of kathode rays. The two latter methods are comparatively simple, because they depend on the observation of luminous effects, but although they agree with each other fairly well, they furnish a value of $m/e$ which is about 1/1000 of that calculated from electrolytic phenomena. It becomes, therefore, a matter for inquiry whether in the former experiments the atom carries a charge greater than that required by Faraday's laws, or whether the charge is carried by a portion only of the atom—in other words, whether a small fraction of the mass of the atom is detachable which has associated with it a negative charge. The simplest crucial experiment is obtained by determining separately either $m$ or $e$, and the author has devised a means of measuring the latter quantity. He takes a negatively charged metal plate supported horizontally; below this and parallel to it is a very large perforated metal plate, the whole being in rarefied gas at a pressure of about 1/100 mm. mercury. When ultra-violet radiation is directed through the perforated plate to strike the upper plate the latter is discharged, the discharging particles moving along straight lines normal to the two plates. If a magnetic field be now excited with its lines of force parallel to the plates, the particles describe curved paths which are in fact portions of cycloids. When the plates are near together the particles which leave the upper one strike the lower one; if, however, the plates are separated further, the vertex of the cycloidal path comes between them, and the particles do not reach the lower plate, so that the discharge ceases. In the actual experiment there is a gradual, but not abrupt, change in the rate of discharge, possibly because all the particles do not start from the surface of the upper plate. From observations on the distance apart of the plates when the change in the rate of discharge commences, the form of the cycloidal path is determined, and the results show that the smaller value of $m/e$ is applicable to this case and to that of illumination by kathode rays. Further, the amount of electricity discharged by the illuminated plate per second is proportional to the number of particles between the plates, to the charge carried by each ($e$), and to the velocity of the particles. The last-named quantity is measured by a method due to Prof. Rutherford, so that if the total number of particles in the space is known the value of $e$ can be determined. To count the particles use is made of the fact that they serve as nuclei for the formation of drops out of a condensing vapour, each particle giving rise to one drop. Let a known amount of air of given humidity be suddenly and definitely expanded in the presence of the particles, and observe the rate at which the drops fall; this rate gives the size of the drops, and hence their mass, and since the whole mass of water deposited is known, the number of drops is thus determined. For negative charges the ratio $m/e$ is independent of the nature of the gas, whereas for positive charges its value varies from one gas to another, and corresponds generally with the values given by electrolytic phenomena. Prof. Thomson considers that electrification consists in the removal from the "atom" of a small corpuscle with which the negative charge is associated; the remaining large portion of the mass is positively charged. This view is supported by Prout's hypothesis that the mass of an atom is not invariable, and by the evidence derived by Lockyer and others from spectroscopic observations.

In the discussion which followed upon Prof. Thomson's paper, M. Broca described spectroscopic observations of a spark obtained between two platinum electrodes ½ mm. apart in a Crookes' vacuum tube; the spectra of the regions near the electrodes and the space between them were not alike. Prof. Rücker drew attention to Schuster's experiments, in which the spectrum of a substance not present in the material examined sprung into being in the arc itself. He believed matter to be a

complicated collection of units themselves similar. Sir Norman Lockyer said that if we accept the view that elements of smallest atomic weights should appear first in the spectrum of a hot star, we must assume the existence of forms of calcium, magnesium, iron and copper having atomic weights which are submultiples of those assigned to them in ordinary chemistry. Further, the division of the spectra of certain elements into series of lines by Rydberg, Runge and Paschen, and others indicates that the atoms of these elements are complexes; we have, therefore, no reason to suppose that the so-called "atoms" are not dissociable at high temperatures. Prof. Oliver Lodge thought the investigations of Prof. Thomson might turn out to be the discovery of an electric inertia, and lead to a theory of mass. Several speakers expressed their pleasure in receiving the members of the French Association.

In the very short time remaining after the discussion on the previous paper, Prof. Oliver Lodge gave a short account of the controversy respecting the seat of Volta's contact force.

On Monday the Section was subdivided for papers on mathematics and meteorology respectively. In the latter department, over which Sir George Stokes presided, a formal report was presented by the committee on solar radiation. Dr. van Rijckevorsel read a paper in which he traced an intimate connection between the activity of sun-spots and the temperature. The committee on seismology presented a voluminous report on their work, from which it appears that twenty-three stations are now equipped with recording seismographs, and registers have been received from ten of these. Notes on these registers occupy a considerable portion of the report; the rest of the report is abstracted from articles which have already appeared in NATURE (February 16 and March 1, 1899). Mr. T. F. Claxton communicated the preliminary results of a year's work with the seismograph at Mauritius. The diurnal waves are of greater amplitude than at any other observing station, and there is a well-marked bi-diurnal effect possibly connected with barometric pressure. Rapid and large changes of the vertical have occurred on several occasions, in addition to a constant gradual change. Air tremors have given trouble at night. The earthquake effects have been of disappointingly small amplitude, and it is suggested that the ocean may act as a damper to earthquake shocks.

Mr. A. L. Rotch gave an interesting account of the progress achieved during the past year at Blue Hill, Massachusetts, in the exploration of the air with kites. The Hargrave kite with curved surfaces has been found more satisfactory than any other form, and the meteorograph records temperature, humidity, height and wind. Temperature is found to decrease at first with elevation, and afterwards to increase again. The heights attained were on the average greater than in previous years. The author mentioned that the United States Government has arranged for daily simultaneous observations at two heights in the case of a number of stations, the kite being used for the high-level observations. The results are not quite satisfactory, because kites could not be sent up on some days; it is suggested that on such occasions a captive balloon be employed. Prof. Thomson hoped that the variation of atmospheric electric potential would be investigated by means of kites. Prof. G. H. Darwin regretted that on account of the non-existence of a Government meteorological observatory, this country is very backward in the adoption of recent methods of meteorological research. In a subsequent paper Mr. Rotch gave an account of the first crossing the Channel by a balloon, by Dr. Jeffries and M. Blanchard in January 1785. The former was a Harvard graduate in medicine, who settled in London, and the latter a French professional aëronaut. The expedition was of a scientific character.

A description of the hydro-aërograph, an apparatus invented by Mr. F. Napier Denison for registering small fluctuations of level of the American lakes and simultaneous small changes of air-pressure, was read by Mr. W. N. Shaw. The apparatus is designed to study more minutely an observed effect of barometric changes on the surfaces of the great American lakes.

The Ben Nevis committee presented the usual summary of their records, and stated that the conclusions arrived at last year with reference to the effects of approaching cyclones and anti-cyclones on the two observatories are supported by the examination of later records. The committee on meteorological photography reported having obtained photographs of some rare forms of cloud and some studies of lightning flashes; the structure of thunderclouds appears to resemble two parallel discs of cloud, with lightning flashes passing between them or from one face to the other of either cloud.

On Tuesday, Prof. Threlfall described a portable gravity balance, designed by Prof. Pollock and himself, for the measurement of small differences in the intensity of gravity from place to place. It consists of a light wire attached near one end to the centre of a horizontally stretched and twisted quartz fibre, the moment of the weight of the wire just balancing the torsional moment of the fibre. The wire is only just in stable equilibrium, and the torsion of the fibre is noted when the wire is adjusted to coincide with the axis of a microscope carried on the frame of the apparatus. The instrument can now be relied upon to 1 part in 500,000, but the accuracy of single readings is greater than this. It has been severely tested by much travelling on the Australian coast.

The committee on electric standards reported that Profs. Ayrton and J. V. Jones have now completed the plans and specifications for the ampere balance to be used in constructing an ampere standard. The committee will consider the proposals of Prof. Callendar for the construction of a standard platinum thermometer in terms of which all other platinum thermometers can be compared. The report contains the results of a determination of the coefficient of expansion of porcelain, by Mr. T. G. Bedford, which was undertaken in order to compare the scales of temperature and platinum thermometers of air.

Prof. Callendar opened a discussion on platinum thermometry, in which he advocated the adoption of the variation of resistance of platinum as a basis for a *practical* scale of temperature. He suggested the construction of a standard thermometer from a particular sample of platinum wire, and the use of a parabolic difference formula for the determination of temperature by its means. The difference-coefficient may be obtained by using as a secondary fixed point the boiling point of sulphur (444·53° C. at normal pressure). Dr. J. A. Harker described the method used, and Dr. Chappuis the results obtained, in a comparison of platinum and nitrogen thermometers at the International Bureau of Weights and Measures at Sèvres. The results agree fairly well with those of Callendar and Griffiths in the comparison of the air and platinum thermometers. In the discussion Mr. E. H. Griffiths advocated the use of the platinum thermometer on the ground that only three readings are necessary in order to standardise any instrument. Prof. Carey Foster was of opinion that the electrical method would furnish a good intermediate standard; for absolute values, however, the gas thermometer must be used, because there is no theory of the variation of electrical resistance with temperature and only an empirical knowledge of it. Prof. Burstall described experiments supporting the proposals of Prof. Callendar. Principal Glazebrook thought that, before taking platinum as a standard, experiments should be undertaken to ascertain whether it is superior to other metals, for instance gold. Dr. Chree said that some platinum thermometers purchased by the Kew Observatory had exhibited curious tricks, and were far from satisfactory, because the reasons for departure from accuracy were numerous and not always discoverable. In the case of mercury thermometers the zero certainly alters, but the change has a known cause, and can be allowed for. Prof. Threlfall remarked that for rapid and accurate work the platinum thermometer alone could be used; the enormous heat-capacity of a mercury thermometer rendering it quite unserviceable. Mr. W. N. Shaw thought the thermo-electric couple methods, upon which the Germans are concentrating their attention, ought to be compared with the platinum thermometer before deciding upon a standard. In reply, Prof. Callendar said that methods based on the use of a thermo-electric couple are not sensitive at low temperatures.

On Wednesday, Dr. L. A. Bauer described the arrangements made by the United States Coast and Geodetic Survey for the proposed magnetic survey of the United States and Alaska, and expressed a hope that the Canadian Government would consider the possibility of a simultaneous survey of Canada. Dr. Bauer also described the results of a magnetic survey of Maryland. Dr. E. P. Lewis, in a paper on the spectral sensitiveness of mercury vapour in an atmosphere of hydrogen, described the appearance and intensity of the spectrum of a mixture of hydrogen and vapour of mercury in varying proportions. Mr. J. Gifford, who has measured the angles of prisms of quartz and calcite, and the corresponding minimum deviations for the mean of the sodium lines, at various temperatures, gave an account of the variation of refractive index with temperature in these cases.

The proceedings of the Section closed with votes of thanks to the president and secretaries, proposed by Prof. Forsyth, and seconded by Prof. Reinold.

## *UNIVERSITY AND EDUCATIONAL INTELLIGENCE.*

OXFORD.—The following are among the lectures and practical courses announced for the present term:—General Pathology, Sir J. Burdon-Sanderson; The Chemical Processes of the Body, Prof. F. Gotch; Elementary Physiological Chemistry, W. Ramsden; Practical Histology, G. Mann; Elementary Medicine. W. Collier; Minor Surgery, A. Winkfield; Human Osteology, Prof. A. Thomson; Analytic Theory of Plane Curves, and Synthetic Theory of Plane Curves, Prof. W. Esson; Elementary Mathematical Astronomy, Prof. H. Turner; Physical Crystallography, Prof. H. Miers; Practical Crystallography, H. Bowman; Electricity and Magnetism, Prof. A Love; Theory of Numbers, Prof. E. Elliott; General Morphology, and Variation Inheritance and Natural Selection, Prof. W. Weldon; Experimental Physics, Prof R. Clifton; Structure of Simple Machines, Rev. F. Jervis-Smith; Silicon and Boron Compounds, Prof. W. Odling; Subjects of the Preliminary Examination in Chemistry, Dr. W. Fisher; Organic Chemistry, J. Watts; Physical Chemistry, V. Veley; Metabolism, J. Haldane; Muscular Activity, Prof. F. Gotch; Physiological Physics, G. Burch; Physical Geology, and Jurassic Fossils, Prof. W. Sollas; Elementary Botany, Prof. S. Vines; Classification of Mankind by Race, Language and Civilisation, Prof. E. Tylor; Bacon, and the Organon of Aristotle, Prof. T. Case; Mental Evolution, G. Stout; Inference and Scientific Method, J. Cook Wilson.

CAMBRIDGE.—Mr. John Sealy Edward Townsend, who entered the University as an Advanced Student in Physics, was on October 9 elected to a Fellowship in Trinity College.

Dr. W. E. Dixon, late Salters' Research Fellow in Pharmacology, has been appointed Assistant to the Downing Professor of Medicine.

Dr. L. Humphry has been appointed Assessor to the Regius Professor of Physic.

A Scholarship of 50*l.* in Natural Science will be open for competition at Downing College to members of the University of less than four terms' standing on Monday, November 27. Applications are to be made to the Tutor.

Studentships for research have been awarded at Emmanuel College to R. G. K. Lempfert and B. W. Head.

---

A GENERAL meeting of Convocation of the University of London was held on Tuesday to receive an interim report from the special committee appointed on June 27 to make representations to and to confer with the London University Commissioners, the Senate, and other bodies with reference to the scheme of the Royal Commission. On the subject of faculties contemplated under Section 10 of the Schedule of the University of London Act, the special committee made various recommendations, among which the following may be noticed:—There should be only one faculty of science with adequate representation on the Senate and the Academic Council. Engineering should be a distinct branch of the one faculty of science and not a separate faculty, but degrees should be given in engineering bearing a distinctive name. If it should be thought expedient to constitute a distinct branch of the faculty of science for any other scientific profession, there is not, in the opinion of the committee, any present occasion for giving a distinctive name to degrees to be taken in that branch. If, contrary to the opinion of the committee, the subjects of the faculty of science should be divided by the commissioners, for electoral purposes, into several faculties, the committee hope they may be afforded an opportunity of giving further consideration to the principles upon which such division should be effected, especially in connection with the effect which the division would have upon the University examinations and degrees. After discussion it was decided "that the report be received subject to the reconsideration by the committee of such points, if any, as this house may deem advisable."

## *SOCIETIES AND ACADEMIES.*

PARIS.

Academy of Sciences, October 2.—M. van Tieghem in the chair.—The Mayor of Chantilly informed the Academy that the inauguration of the statue erected to the Duc d'Aumale would take place on October 15.—Orbit of the shooting star of August 24, by M. J. Comas Sola. This meteor, which was a very bright one, was observed at the Observatory of Català, had a relative direction nearly east to west, disappearing near $\alpha$-Capricorn. Its absolute velocity was 50 kilometres per second. A similar meteor was observed on August 28 at 7.45, but of smaller lustre.—On the identity of solution of certain problems of elasticity and hydrodynamics, by M. Georges Poisson. In a note presented to the Academy on May 2, 1898, M. Maurice Lévy remarked that in problems of elasticity in two dimensions the distribution of the pressures is independent of the value of the elastic coefficients. In the present note it is shown that in this case the determination of the pressures may often be reduced to the study of the permanent motion of a liquid.—On two chlorobromides of tungsten, by M. Ed. Defacqz. In an attempt to prepare tungsten hexabromide, tungsten hexachloride was sealed up with liquid hydrobromic acid in excess, and the whole heated at 70° for four hours. The resulting product was not the desired hexabromide, but a chlorobromide having approximately the composition $WCl_6.3WBr_6$. In a second similar preparation the tube was not heated, but left for three days at the temperature of the laboratory; the substance obtained was another chlorobromide, represented by the formula $WCl_6.WBr_6$.—On copper hypophosphite and its decomposition by precipitated palladium, by M. R. Engel. Aqueous solutions of copper sulphate and barium hypophosphite are mixed in equal molecular proportions, the solution filtered, and the copper hypophosphite precipitated in the crystalline form by the addition of alcohol in excess. The solution of the salt is decomposed in a remarkable manner by the addition of precipitated palladium, copper being thrown down and hydrogen gas evolved according to the equation

$$Cu(PO_2H_2)_2 + 2H_2O = Cu + 2H_3PO_3 + H_2,$$

no copper hydride being formed. In the absence of palladium the copper hypophosphite is decomposed differently by heat, copper hydride being first formed, and then metallic copper, phosphorous and hypophosphorous acids.—Salicylic and paraoxybenzoic aldehydes and salicylhydramide, by MM. Delépine and Rivals. A thermochemical paper.—On a double monstrosity observed in the blastoderm of a fowl's egg in the course of formation, by MM. Bonmariage and Petrucci.—Completion of some observations on the Alps of the Vaudois, by M. Stanislas Meunier.—On an aërial voyage of long duration, from Paris to the Mediterranean, carried out on September 16 and 17, by M. Gustave Hermite.—Barometric deviations on the meridian of the sun on successive days of the tropical revolution of the moon, by M. A. Poincaré.

## *ELECTRO-MAGNETIC THEORY.*

*Electro-magnetic Theory*. Vol. ii. By Oliver Heaviside. Pp. xvi + 542. (London: The *Electrician* Co., Ltd.)

THIS interesting work, the first volume of which appeared some five years ago, well sustains Mr. Heaviside's reputation as an original investigator, and even when we do not agree with his procedure, we must admire his fertility of resource and the skilful manner in which he develops his methods. Although we are more than once warned that the treatment is not formally or logically arranged, as is indeed the case, Mr. Heaviside has nevertheless, in essentials, admirably arranged his matter, so that we are led on by gentle steps from comparatively simple to more complex problems.

The book may be regarded from two distinct points of view. Firstly, without inquiring too closely into the validity of the mathematical methods employed, we may consider the work from a physical point of view as a mathematical theory of the propagation of plane electromagnetic waves in conducting dielectrics, according to Maxwell's theory, or as the theory of the propagation of waves along wires. Secondly, we may consider the book from a purely mathematical point of view as an introduction to the theory of generalised differentiation, divergent series, and Bessel's functions, viewed, however, for the most part through physical spectacles.

The book opens with a discussion of the age of the earth, in which Prof. Perry's results are explained and contrasted with those of Lord Kelvin. Then follows a discussion of the equations

$$-\frac{dV}{dx} = RC, \qquad -\frac{dC}{dx} = SpV$$

where V and C are the voltage and current, R and S the resistance and permittivity per unit of length, and $p$ stands for $\frac{d}{dt}$. A large number of problems are considered in some detail, and it is very noticeable how easily terminal conditions are dealt with by Mr. Heaviside's methods, and in this respect they have a great advantage over Fourier's method. The more general equations

$$-\frac{dV}{dx} = (R + Lp)C, \qquad -\frac{dC}{dx} = (K + Sp)V$$

where L is the inductance and K the leakance, as Mr. Heaviside terms it, per unit of length, are next considered. These in the case where $1/R$, $1/L$, K and S all vary as the $n$th power of the distance from $x=0$ lead to Bessel's functions. As before, a great variety of interesting and important questions are dealt with, and Mr. Heaviside is careful to explain that these are not mere mathematical exercises, but that the formulæ apply to cylindrical electro-magnetic waves. The case of R, L, K, S, constants is discussed at some length, and owing to the application of the results to practical questions concerning telegraph and telephone cables they should be kept in mind by "practicians." Mr. Heaviside has for long been preaching in the wilderness on this matter, but his labours will bear fruit one day, and we trust that when the day comes it will not be a case of "tulit alter honores," as has happened to other men in other matters. Some sections are devoted to discussions of the experiments of Dr. Barton and Dr. Bryan, of spherical waves, and, with some reserve, to the experiments of Hertz and Lodge. The sections on spherical waves have, as is pointed out by the author, a practical application in wireless telegraphy. Some rough, but interesting, curves showing the progress of a wave under various circumstances conclude the physical portion of the work.

Passing on to the mathematical aspect of the book, operational methods are freely employed, and their reduction to algebraical form leads us at an early stage of the work to the question of fractional differentiation. This is a subject which has frequently occupied the attention of mathematicians, and two main modes of proceeding have been proposed, one taking $e^x$, the other $x^n$ as the fundamental symbol; the first method was employed by Liouville and Kelland, the second by Peacock. Both methods find formulæ which are certainly true when the index of the operating symbol is an integer, and for the case of the index or fraction both appeal to the principle of the permanence of algebraical forms. If both methods produced the same result in every case all might be well, but most unfortunately this is not so, at least without some further assumption, and it is a question beset with difficulties which system, if either, is to be considered the true one. Mr. Heaviside's method evades rather than elucidates the difficulties. He requires to find the value of $p^{\frac{1}{2}}1$, where $p = \frac{d}{dt}$, and 1 is that function of $t$ which is zero before and unity after $t=0$. To effect this he takes a suitable physical problem, and, solving symbolically, obtains a solution involving $p^{\frac{1}{2}}1$; then by another method he finds a solution free from operators; a comparison of the two gives $p^{\frac{1}{2}}1 = (\pi t)^{-\frac{1}{2}}$. This is the same value as is given by Peacock's method, but not that which is given by Liouville's and Kelland's without further assumption. In Chapter vii. another way, on the same lines as before, is given of finding this result, and the remark is added, "I do not give any formal proof that all ways properly followed must necessarily lead to the same result." It is much to be regretted that no hint is given on this point, for, granting that there is a theory of fractional differentiation, the way to be properly followed is the essence of the whole matter.

Some of Mr. Heaviside's methods of dealing with series in Chapter viii. are also open to some objection; he more than once tests the equivalence of two series by giving the variable numerical values and seeing if the two series give the same result. This may be an "excursion to the borders of the realms of duplicity," but scarcely to those of "fearful rigour." It would seem, indeed, from many passages in the book, that Mr. Heaviside considers rigour in mathematics to be of somewhat minor importance; for instance:

> "You have first to find out what there is to find out. How you do it is quite a secondary consideration."

If this advice were to be generally followed, mathematicians would no doubt jump many gates in their endeavours to reach the goal on the other side, but whether or no they would not at times land in a quagmire may be open to doubt.

Mr. Heaviside's treatment of Bessel's functions is interesting and suggestive, but the lack of formal arrangement is here severely felt; it is not always easy to distinguish clearly between what is proved and what is experimentally assumed to see how it goes as Mr. Heaviside puts it. The student who is previously unacquainted with the properties of these functions will probably find difficulty in following some of the equations written down without proof. In the equation for $K_0 (qx)$, p. 226, for example, all the information given about $\gamma$ (Euler's constant, but not distinguished as such) is "where $\gamma = 0{\cdot}5772$ is a certain constant introduced to make $K_0 (qx)$ vanish at infinity"; certain of the conjugate relations are also without proof, but these possibly are left as exercises for the student.

The work is nevertheless one which will well repay careful attention. As has been remarked by Prof. De Morgan:

"The history of algebra shows us that nothing is more unsound than the rejection of any method which naturally arises, on account of one or more apparently valid cases in which such methods lead to erroneous results. Such cases should indeed teach caution, but not rejection."

Mr. Heaviside is much to be congratulated on the light he has thrown on difficult and perplexing questions in both physics and mathematics, and also for calling the attention of mathematicians to a powerful, but somewhat neglected, weapon. C. S. WHITEHEAD.

## OUR BOOK SHELF.

*Catalogue of the Lepidoptera of Northumberland, Durham and Newcastle-upon-Tyne.* Part I. By J. E. Robson. *Nat. Hist. Trans. of Northumberland, Durham and Newcastle-upon-Tyne*, Vol. xii. Part 1. Pp. 195.

THE present instalment of this important catalogue includes the butterflies, together with such of the moths as are comprised in the *Sphingina* (hawk-moths), *Bombycina*, and *Noctuina*. In his classification the author thus far follows Mr. Barrett's monograph of the British Lepidoptera, to the unpublished portions of which he has been supplied with references by Mr. Barrett himself. Whatever faults there may be in the scheme of classification in question, and the nomenclature employed therein, the adoption of a uniform system by different writers is highly desirable; and we, therefore, consider that Mr. Robson has been well advised in the course he has adopted.

As the author has had the advantage of the cooperation of all the local collectors of repute, his work may be regarded as a thoroughly up-to-date account of the Lepidopterous fauna of the northernmost counties of England. And how different this fauna is from that of the midland and southern counties may be gathered from a glance at the portion devoted to the butterflies. The common Brimstone Butterfly, for example, is only known in the area treated of by two or three stragglers, its normal range not extending northwards of South Yorkshire. Much more remarkable, however, is the circumstance that certain species of butterflies, such as the Comma and the Red Admiral, which were once common in the two counties, have for the last forty years been extremely scarce, although the second of the two mentioned has once again become a familiar object since 1893. It would be interesting to know the reason why so many of these insects left the district during the sixties; but on this point the author is silent. On the other hand, as might perhaps have been expected, migratory species, such as the Clouded Yellow and the Camberwell Beauty, which visit England at uncertain intervals in larger or smaller numbers, commonly travel into the northern counties; the author remarking of the last-named insect that it "visits these counties on most of those rare occasions when a wandering horde strikes our shores." Of the moths, it must suffice to say that the Death's-head has occurred in both counties, and there is reason to believe has bred in them, but that the stock is probably maintained by immigration from the south.

The foregoing instances demonstrate that Mr. Robson's work is very far from being a mere dry catalogue; and that it really teems with interesting observations on the life-history and distribution of all the species recorded. If the sequel be maintained at the same high level, the complete catalogue ought to prove a very important contribution to entomological literature. R. L.

*The Process Year-Book for* 1899 ("Penrose's Pictorial Annual"). Edited by William Gamble. Pp. viii + 108. (London: Penrose and Co., 1899.)

THIS is the fifth year's issue of this most excellent review of the graphic arts, and the editor, together with all his co-workers, are to be congratulated on the production of such a handsome and interesting volume.

As in former years, most of the articles are written by those who are at work in some line of process work, and as these are by no means few in number, the reader is made acquainted with a great amount of experience which may help him to success in the future. The feature of the book is undoubtedly the beautiful illustrations, which bring home to the reader the high state of excellence that the art of reproduction has reached at the present day. All kinds of subjects, from a stellar cluster down to an orchid, are illustrated, and these serve as types for showing the results obtained by the working of different processes.

The high order of merit attained should not only render the book a valuable aid to the process worker and others interested in the art of reproduction, but should find many other friends who would delight to possess such a charming collection of high-class illustrations.

*Mathematical Tables.* By James P. Wrapson and W. W. Haldane Gee. Pp. 28. (London: Macmillan and Co., Ltd., 1899.)

THIS set of useful tables in a compact form are abstracted from the compilers' larger volume of "Mathematical and Physical Tables." The idea of this present issue is to place before students tables which are suitable for the class and laboratory, and which give sufficient accuracy for such computations.

To sum up the contents, we have four place logarithms and antilogarithms, natural sines, cosines, and tangents, with interpolation to 1′. Logarithmic sines, cosines, and tangents with differences also to 1′. Tables of squares, exponential functions, weights and measures, and finally a table of conversion for the last mentioned.

*Opinions et Curiosités touchant la Mathématique.* By G. Maupin. (Paris: Carré et Naud, 1898.)

THIS is a collection of curious ideas and essays, which the author has encountered in the course of much heterogeneous reading in ancient scientific works, in which there has been found any reference however remote to mathematical thought. Paradoxes and absurdities alone seem to be considered worth inclusion; the book is of little or no use as a contribution to the history of mathematics.

## LETTERS TO THE EDITOR.

*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

### Peripatus in the Malay Peninsula.

MY friend Mr. Richard Evans, of Jesus College, Oxford, now in the Malay Peninsula with the Skeat Expedition sent out by the University of Cambridge, writes to me that he and subsequently other members of the expedition have discovered Peripatus. His letter, written from Aring, Kalantan, and dated August 27, states that he had found two specimens about three months previously. The locality is given as "one of the mountains here." For some months after this discovery no further specimens were found, in spite of much searching. A little before the date of his letter, however, Mr. Laidlaw, of Cambridge, had found five and Mr. Evans six additional specimens, thus bringing up the number to thirteen.

The eleven specimens which were obtained last were found in two groups of five each, while a single individual was discovered by itself in the rotten tree in which one of the groups occurred.

The individuals of a group differed much in size, although each group was probably a brood.

The colour of the specimens is chocolate-brown above with numerous small pale spots, the under-surface being pinkish yellow with a nearly white spot between the feet of each pair.

The number of pairs of feet varies from twenty-three to twenty-five, the latter number occurring in the largest and presumably the oldest specimens.

Mr. Evans has asked me to embody these facts in a note to NATURE, and I feel sure that they will be of great interest to all naturalists. EDWARD B. POULTON.

Oxford, October 13.

### Dark Lightning Flashes.

THE paper by Mr. A. W. Clayden, referred to in my lecture from which Dr. Lockyer quotes (p. 570 *ante*), is entitled "Note on some Photographs of Lightning and of Black Electric Sparks," and is to be found in the *Proceedings* of the Physical Society, vol. x. p. 180, having been read on June 22, 1889. The author's photographs were exhibited at the meeting, but were not printed with the paper.

The following extract shows that some of Mr. Clayden's observations were very similar to those described by Dr. Lockyer. He photographed some electric sparks of different intensities, "and before developing the plates exposed them to the diffused light from a gas flame. The brilliant sparks then yielded images which may either be called normal with a reversed margin, or reversed with a normal core. The fainter sparks were completely reversed. . . . The reversal seems to spread inwards as the exposure to diffused light is increased." If the section of a flash is approximately circular, the luminosity would naturally be greatest along the middle, gradually falling off towards the edge.

It was of course known long before the date of Mr. Clayden's paper that the bright parts of a photograph might be reversed by the action of diffused light before development (Sutton's "Dic. of Photography," edition of 1867, p. 299).

I think it hardly possible that any lightning flash would be sufficiently brilliant to give a photographic image with a dark core and bright edges—Nos. 5 and 6 of Dr. Lockyer's list. The image of the sun itself is not generally reversed, unless with comparatively long exposure. The picture in the *Strand Magazine* (vol. xiii. p. 44, Fig. 10), which I understand to be the only apparent example of this class of reversal which Dr. Lockyer has met with, seems to me, from considerations of perspective, to represent beyond question merely a close double flash, two connected discharges having taken the same path through a moving body of air.

Dr. Lockyer's convincing article has no doubt finally disposed of the dark flash as an objective reality. It is to be hoped that so-called "ribbon lightning" will soon follow in its footsteps. SHELFORD BIDWELL.

### Heredity and Variation.

THE interesting suggestion made by Prof. Adam Sedgwick in his Dover address—to the effect that variability has decreased and heredity increased, so to speak, as evolution has progressed—leads me to call attention to the work of certain other writers. Prof. Bailey, of Cornell University, in his work "The Survival of the Unlike" (Macmillan) argues in detail for a similar view, *i.e.* that heredity has been gradually "acquired," while variability has been reduced. His book deals largely with evidence from plants. He stated the view earlier in certain papers. Moreover Prof. Williams, of Yale University, independently took up a like position at about the same time in several papers, the latest one having been read and discussed before the Society of American Naturalists at Ithaca, N.Y., December 1897, and subsequently printed in *Science*.[1] The point of view has become fairly familiar to American biologists. Indeed the editor of *Science* has referred to it as one of the two most important recent suggestions in the theory of evolution. As Prof. Sedgwick does not refer to these writers—though he may intend to do so in the fuller discussion which he promises—his readers to whom the suggestion appeals may find it worth while to look into them. The work of Prof. Bailey—who is a natural selectionist among botanists!—is remarkable from other points of view as well.

Oxford, October 10. J. MARK BALDWIN.

[1] I regret that absence from my library makes it impossible for me to give the exact references to his papers and to Prof. Bailey's.

### Phosphorescent Earthworms.

IN a recent issue of NATURE (during May of the current year) Mr. Beddard, in referring to the phosphorescence of *Microscolex* (*Photodrilus*) and of *Allolobophora foetida*, suggests that this phenomenon is exhibited by the slime secreted by the epidermis. Will you allow me to mention my observation on a New Zealand worm that indicates that the matter is worthy of re-investigation?

Our large white earthworm (*Octochoetus multiporus*) has a milk-coloured cœlomic fluid of very great tenacity; it can be drawn out into strands, and soon hardens on exposure to air. In the dark, when the worm is handled, this fluid is discharged abundantly from the dorsal pores and from the mouth, which it reaches through the "peptonephridia" opening into the buccal cavity. The fluid is brilliantly phosphorescent when freshly discharged, and the fluid sticks to one's fingers very persistently; but it soon loses its phosphorescence. I wish here merely to point out that the luminosity is due to the cœlomic fluid in *O. multiporus*, and I believe that further examination will show that the same is true of *A. foetida*.

The fluid in *O. multiporus* contains numbers of "elæocytes," which are present also in *A. foetida* and other European worms; but in the New Zealand worm they are colourless, not yellow. A very remarkable kind of corpuscle is also present, viz. a cell containing a threadlike structure not unlike those described by Goodrich in an enclytrœid a few years back. I am now endeavouring to locate the phosphorescence—that is, to ascertain which of these two cells is the seat of the phenomenon.

Dunedin, N.Z., August 5. W. BLAXLAND BENHAM.

## MEETING OF THE INTERNATIONAL METEOROLOGICAL COMMITTEE.

THE Committee met at St. Petersburg from September 2–7; the meeting was a small one, only about half of the members being present. It was opened by the Grand Duke Constantine, who delivered an interesting address, in which he specially referred to the service rendered to meteorological science by A. Kupffer, the founder of the Russian climatological organisation. The reports of the various sub-committees were read and considered, and the following are the principal resolutions arrived at:—On the report, by Prof. Rücker, upon terrestrial magnetism and atmospheric electricity, it was decided that the sub-committee should be maintained as a distinct organisation, under the direct supervision of the International Committee. In reply to a question by

General Rykatcheff, director of the Russian Meteorological Service, the Committee recommended that meteorological institutions should take part in observations of earthquake phenomena. With regard to Antarctic exploration, the Committee expressed the opinion that it is highly desirable (1) that the results of these explorations should be completed by data from the observatories already existing in the southern hemisphere, and by those made on board vessels traversing the southern oceans; (2) that new meteorological stations should be established in the southern part of the Antarctic regions, and especially that magnetic observations should be organised; (3) that magnetic determinations over the whole globe should be made simultaneously with those made during the expeditions. With reference to the valuable researches of Dr. Hildebrandsson relating to the great centres of action of the atmosphere (which have already been noticed in our columns), the following resolution was adopted:—"The Committee appreciates the high interest attached to observations made in a regular manner in different regions which seem to possess special importance as to our knowledge of the general laws of the motions of the atmosphere." Profs. v. Bezold and Mascart drew attention to the proposed establishment of a very complete meteorological and magnetical observatory at the Azores by the Prince of Monaco, assisted by Captain Chaves, of the Portuguese navy, who has entirely devoted himself to the realisation of this undertaking. On the question of the calculation of daily meteorological means, it was decided that if the exact formula

$$\frac{0+24}{2}+1 \ . \ . \ . \ +23:24$$

is not adopted the midnight observation should be taken into account at the end of the day, as is already done at most stations, according to the formula

$$1+2+3 \ . \ . \ . \ +24:24.$$

On the proposal of Dr. Hann to publish tables of diurnal range of temperature for each country in a special form, the Committee, while appreciating the interest and importance of the proposal, expressed its opinion that, as the question possessed a general bearing, it should be examined by a sub-committee, which should determine the form of table to be adopted by all countries. On the subject of the importance of actinometric observations, also brought forward by Dr. Hann, the Committee expressed the hope that the sub-committee for terrestrial and solar radiation would present a report upon that subject at the next International Congress. M. Violle submitted a note on the various methods employed for actinometric measurements. On the proposal of Dr. Pernter as to the desirability of the restriction of observations with the wet-bulb thermometer and the multiplication of observations with the hair hygrometer, the Committee came to no decision, pending the presentation of a full report upon the question. Dr. Paulsen, director of the Danish Meteorological Institute, drew attention to the importance for weather prediction of the laying of a cable between Iceland and Europe, towards which the Danish Government and the Great Northern Telegraph Company were prepared to make a considerable annual subvention. The Committee fully recognised the importance of the proposal, and expressed its hope of the ultimate success of the project. Profs. Neumayer and v. Bezold made a proposal relative to the publication of an international periodical weather report (recently referred to in our columns), which should contain ten-day means from about a hundred stations. The Committee was of opinion that it would be desirable that a definite plan of the proposed publication should be prepared for examination by each meteorological service. A sub-committee, composed of MM. Pernter (president), Billwiller, Neumayer, Rykatcheff, Mohn and Tacchini, was nominated for the purpose of considering the extension and improvement of international telegraphy for weather prediction. Finally, it was decided that the International Meteorological Committee and the various sub-committees should meet in Paris in the year 1900, immediately after the Meteorological Congress which will take place on the occasion of the Exhibition. This Congress will probably be held during the first half of September. We are indebted to M. Lancaster's summary in *Ciel et Terre* for the notice of this meeting.

## *THE COMING SHOWER OF LEONIDS.*

DURING the past few years English observers, in their efforts to witness returns of the Leonid meteors, have met with little but disappointment. Either the firmament has been overcast at the important time, or the display has been very weak. The rarity and singular attractiveness of a really fine meteoritic exhibition are such that the immediate prospect of viewing an event of the kind has aroused great interest in the whole subject of shooting stars. But we have been a little premature in our anticipations in recent years, and looking for the appearance of the meteors before the vanguard of the denser portion of the stream had begun to cross the earth's path. There can, however, be no doubt as to the character of the ensuing display. The earth will be sure to encounter one of the richest regions of the orbit at the middle of November, but whether or not this collision will occur at an hour perfectly suitable for its observation remains to be seen. It must be admitted that the exact time of the *rencontre* cannot be definitely stated. The materials upon which computations have to be based are not sufficiently numerous and consistent to enable exact deductions to be drawn from them. Moreover, there is evidence to show that the system of meteors is constantly undergoing changes. The particles are spread out, and are still spreading out, over a very considerable section of the orbit, and are subject to perturbations by the larger planets. Different sections of the stream are affected unequally, so that the whole system, both as regards its conformation and distribution, suffers from such irregular disturbances, that we must be prepared for the visible signs of developments of an unexpected character. In the present state of our knowledge it is impossible for us to allow for all the various circumstances and conditions which control the visible aspect of the shower, from year to year, and modify its orbital elements.

Calculations which have been made independently by several authorities show that the influence of Jupiter and Saturn, since the last return of the shower in 1866, has been exerted in increasing the node, so that the phenomenon may be expected a day late in the present year It will probably occur just before sunrise on November 16. Drs. Stoney and Downing, in a paper published in the *Proceedings* of the Royal Society, vol. lxiv. p. 406, state that a noteworthy outcome of their investigations is that the meteor-group which gave rise to the display in 1866, made a near approach to Saturn in 1870, and to Jupiter in 1898. On the latter occasion the meteor-cloud was distant from Jupiter by an interval of space less than that separating the earth and the sun. Berberich (*Ast. Nach.*, 3526) has also discussed the orbit-perturbations of the Leonid stream, and concludes that the meteors will appear about a day later than they would have done under normal conditions. If there had been the average annual displacement of the node (equal $102''\cdot6$) the recurrence of the shower might have been anticipated on November 15 at about 1 a.m., but the perturbations seem to have increased the longitude of the node to the extent of $1\frac{1}{4}^\circ$; so that the greatest intensity of the display must be awaited on the morning of November 16, in the twilight preceding sunrise.

But it must be admitted that these deductions are liable to some uncertainty. Last year the predicted late-coming of the meteors was far from being corroborated by observation. The maximum number of meteors was recorded on the morning of November 15, and very few Leonids were presented on the following morning, though computation had indicated the latter as the time of maximum. In view of the prevailing doubts there seems no alternative but to watch for the shower throughout the morning of the 15th, and failing its brilliant apparition then, to repeat the watch on the morning of the 16th. The maximum may be displayed at any time between November 15, 0h. 30m. a.m. and November 16, 6h. 30m. a.m.

In England a November sky is cloudy on at least three nights out of four, and this year we shall have moonlight to consider as well, for our satellite will be nearly full, and must largely detract from the striking character of the display. Should the meteors appear on the morning of the 15th, they might, however, be seen on a dark sky, for the moon will set about $2\frac{1}{2}$ hours before sunrise. The Leonids are fine meteors; a large proportion of them are as bright as 1st mag. stars, and, notwithstanding moonlight, will create a conspicuous effect if they return in great numbers. On the occasion of the last grand display on the morning of November 14, 1866, the writer was much struck with the number of tolerably bright meteors, and observed several which were many times brighter than Venus at her best. These Leonid fireballs gave lightning-like flashes, and left short green streaks, enduring for five, ten, fifteen minutes, and even more. The approaching display will be sure to supply a few of these splendid objects.

At every station where the weather enables the shower to be successfully witnessed, certain features ought to be particularly recorded. The meteors should be counted, and the time of maximum ascertained. It will be useful also to determine the hourly rate of apparition by noting at certain regular intervals the number which appear. By counting during short intervals and continuing the work for several hours, the rise and fall of the display as well as the number per minute at and near the time of maximum might possibly be obtained. In the event of an exceedingly abundant display, similar to that seen in America in 1833, the observer may feel bewildered and find it impossible to record the exact numbers. In such a case the figures should be estimated as carefully as possible.

Another feature will be to preserve a description of the time, brightness and apparent paths of any specially fine Leonids that may be visible. The paths should be marked on a celestial globe or suitable star-map, and the Right Ascension and Declination of their beginning and end points registered in a book properly ruled for the purpose. The length, duration and possible drifting of the luminous streak, left by every bright meteor, should also receive attention. Near the time of maximum, however, these details may be disregarded, as it will be necessary for the observer to concentrate his efforts to fixing the time of the maximum and strength of the display. A table with writing material and a lamp should be at hand so that numbers and notes can be hurriedly recorded by the observer almost without diverting his attention from the heavens. With more than one observer the various aspects of a meteoric shower can be fully recorded, but it is impossible to suppose that one person can watch its progress and record all the details presented.

Observers need not specially record the meteors with the main object of fixing the centre of radiation. We have already obtained a great number of eye-estimates of this position, and these must be put aside for the more accurate values obtainable by photography. No doubt the latter method will be extensively brought into requisition, though the bright moonlight will afford

a serious hindrance on the present occasion. The Leonids begin to fall as early as November 7, and the shower is sustained over a fortnight. It will be very important to look for the meteors of this stream between about November 7-11, and record the paths of those visible with a view to definitely ascertaining the position of the radiant. At this early period of the shower's activity it is not probable that the photographic method will be appealed to. It is to be hoped that all regular meteoric observers will follow the progress of the shower with close attention during the second week of November in this year, for the questions as to the date of commencement of the shower and as to whether the radiant is a shifting or stationary one are very interesting features requiring settlement.

W. F. DENNING.

## *NOTES.*

COLONEL J. W. OTTLEY, C.I.E., has been appointed president of the Royal Indian Engineering College, Coopers Hill, in the place of Colonel Pennycuick, C.S.I., resigned.

THE Committee of the British Association Table at the Naples Zoological Station announce that the Table is fully occupied until the middle of April next, but that applications for its occupancy from then until the end of August 1900, should be sent at once to the Hon. Secretary of the Committee, Prof. Howes, F.R.S., at the Royal College of Science, South Kensington. Mr. Kyle will occupy the table from now until Christmas, when he will be succeeded by Mr. M. D. Hill, who will continue investigations on the reproduction processes of Crustacea, and in March Prof. Herdman will go out and devote a month to the study of the Tunicata of the Bay.

THE Harveian Oration was delivered at the Royal College of Physicians by Dr. J. Vivian Poore on Wednesday last.

AN address will be given to the North-west London Chemical Society, on October 24, by Dr. Lauder Brunton, F.R.S., who will take as his subject "Biliousness and Gall Stones." On November 2, Sir J. Burdon-Sanderson will deliver an introductory address to the Middlesex Hospital Medical Society. To this all past and present students of the hospital are invited.

A TELEGRAM from Amsterdam, dated October 12, states that a violent earthquake has occurred in the south side of the Island of Ceram, in the Dutch East Indies, causing the death of some thousands of persons and the complete destruction of the town of Amhei. Details, however, are wanting.

AT a meeting of the Finance Committee of the Lincolnshire County Committee, held on the 13th inst., it was resolved that the County Committee be recommended to give their consent to the erection, within the grounds of Lincoln Castle, of an observatory for the preservation and use of certain astronomical instruments offered to the county by the executors of the late Canon Cross, of Appleby. The recommendation was made that the committee's consent should be given subject to the condition that the buildings shall not be commenced until sufficient funds have been raised for their erection and the future maintenance of the instruments. It is proposed to raise the funds by public subscription. We trust there will be a hearty response to the appeal that is to be issued.

AT a meeting of the Council of the London Mathematical Society it was resolved that the president (Lord Kelvin), the three vice-presidents, the treasurer, and the two secretaries should be nominated for the same offices at the annual meeting on November 9 next. Of the other members, Messrs. W. H. H. Hudson, D. B. Mair, and W. D. Niven, C.B., retire from office, and Messrs. W. Burnside, H. M. Macdonald and E. T. Whittaker were nominated to fill the vacancies. The Council also empowered the secretaries to publish an "Index" to the first thirty volumes of the *Proceedings*, on the lines of the similar index to the first fifty volumes of the *Mathematische Annalen*. Mr. Tucker was further authorised to draw up a complete list of members from the foundation of the Society in 1865.

THE Council of the Royal Photographic Society have decided to institute a series of monthly meetings, extending from November to April, to be especially devoted to illustrated lantern lectures. The meetings will be held on the first Tuesday in the month, and the first will take place on November 7.

THE second Traill-Taylor Memorial Lecture will be delivered on November 14 at the rooms of the Royal Photographic Society by Major-General Waterhouse, who will take as his subject "The Teachings of the Daguerreotype."

THE third International Congress of Photography is to be held in Paris from July 23 to July 28, 1900. Its purpose will be to re-examine decisions arrived at by the two last Congresses on problems before the Society, and to see if such are capable of further improvement or perfection. To inquire into the various new photographic questions arising since the last meeting. Practical demonstrations of working methods, lectures on special subjects, and visits to scientific and industrial institutions also form part of the programme. Those intending to be present are requested to address the General Secretary, M. S. Pector, 9 Rue Lincoln, Paris.

THE magnetic survey of Maryland has now been practically completed, the distribution of stations being such that on the average there is one station for every hundred square miles. The expenses of the work, with the exception of this year, have been entirely borne by the Maryland Geological Survey.

A SCIENTIFIC and commercial mission, under the direction of M. Ernest Milliau, Director of the Laboratory of Technical Experiments in connection with the Ministry of Agriculture, Paris, has been sent to Russia and Roumania with the object of taking measures for facilitating and extending business relations with those countries, especially with regard to the exportation of olive oils.

A BACTERIOLOGICAL institute has recently been established at Vladivostok, and a similar institute is shortly to be opened at Merv in Central Asia.

OWING to the prevalence of enteric fever in Natal, every man ordered for military service in that Colony has, says the *Lancet*, been given the option of being inoculated with anti-typhoid serum, and 70 per cent. of the troops have accepted the offer.

THE late Prof. O. C. Marsh's executors are about to sell his valuable collection of orchids, objects of art, antiquities, &c., for the benefit of the Yale University.

ACCORDING to the *Scientific American*, Japan is to send out an Arctic Expedition. The Japanese Government wishes, says our contemporary, to develop in the Japanese the spirit of adventure and discovery which has rendered the English nation so powerful.

THE New York Zoological Park, situated in Bronx Park, is to be opened to the public this month. The *Scientific American* states that the specimens which will be ready for public inspection will form but a small part of the exhibit, and that these will be very interesting.

THE return, after an absence of two years, of Mr. A. J. Stone, of New York, is announced. Mr. Stone has been travelling in the Arctic regions during the time mentioned, studying the geographical distribution of animals. It is reported that during five months of travel last winter he covered 3000 miles of coast and mountain entirely above the Arctic circle.

*Science* announces the return from Manila of the Johns Hopkins University Commission, which, under the direction of Dr. S. Flexner, has spent the past summer in studying tropical diseases.

THE death is announced, from Vienna, of Dr. Oscar Baumann, who had acquired some reputation as an African explorer. In 1885 Dr. Baumann joined the Austrian Congo expedition, subsequently visiting the island of Fernando Po, the Cameroons, and parts of East Africa. Other expeditions followed, in one of which he fell into the hands of hostile Arabs, and was only released on the payment of a ransom. He was entrusted with

the command of an expedition fitted out in 1889 by a German anti-slavery association. In the following year he explored the Usambara, and made preliminary observations for the purpose of tracing a projected railway in that region. In addition to a map of the Congo and numerous contributions to the reports of the Geographical Society of Vienna, Dr. Baumann published three books dealing with his travels and observations in Fernando Po and Usambara and with the rising in German East Africa.

We regret to notice the death of Dr. J. W. Hicks, the Bishop of Bloemfontein, which has just taken place. The late Bishop was an earnest student of science, and was at one time a demonstrator in chemistry in the University of Cambridge, and published a text-book on inorganic chemistry. He was also a fully qualified medical man, having been made an M.D. in 1864, and an M.R.C.P. in 1865.

The death has occurred, at Adirondacks, New York, of Mr. Hamilton Y. Castner, well known for his work in connection with the manufacture of aluminium and the establishment on a manufacturing scale of a process for the electrolytic production of alkali and bleaching powder from common salt.

The *National Geographic Magazine* states that various sites within a radius of twenty-five miles of Washington are being examined by parties under Dr. Bauer's direction for the determination of the best location for the Coast and Geodetic Survey Observatory. The examinations thus far made have disclosed some interesting regional disturbances, especially in the vicinity of Gaithersburg. In order to determine what influence such regional disturbances have upon the variations of the earth's magnetism, such as, for example, the diurnal variation or the secular variation, it is proposed to mount a sensitive Eschenhagen dedinetograph at Gaithersburg, with the aid of which the variations of the most sensitive of the magnetic elements—the declination—will be continuously and automatically recorded.

The British Fire Prevention Committee made a series of fire tests yesterday at their testing station as we went to press. The tests on this occasion were with a concrete floor, an iron safe, and two doors of wood. We are glad to see that the committee are continuing their valuable work in so energetic a manner. Valuable results may be expected to accrue from the experiments made by the committee from time to time.

A monument erected to the memory of Johannes Müller was unveiled at Coblentz on October 7. Prof. Virchow, who was the principal speaker at the ceremony, said in the course of his remarks that Müller was a biologist, a naturalist whose aim was the study of life itself in its universality. He was the first to use the microscope in researches on living beings, the first to disclose the fauna of the seas. His example inspired the deep-sea researches of to-day. Müller's method was observation; he put things into the right positions for exhibiting their action, and then registered his observations. At the time of Müller's youth it was believed that from inanimate nature, from atoms, from matter, or substance, new combinations might form themselves, which finally might lead to the generation of living organic forms, that, in short, plants and men might be evolved from dust. In modern times this had been named spontaneous generation. Johannes Müller warned against such hypothetic conclusions. He said: "We cannot generate living substance, and as long as we cannot do so, as long as we have no proof, we must put these theories aside"; and (said Prof. Virchow) that is the standpoint of resignation, of submission, that is the true position for a naturalist, such as Muller was. On the occasion of the unveiling of the monument, Muller's daughter presented to the State Library fourteen volumes of drawings, containing upwards of nine hundred zoological sketches made by her father in the years 1850–1854 in various countries.

The Indian correspondent of the *Lancet* states that new regulations have been made with reference to persons sending or taking from place to place in India cultures or other articles known or believed to contain the living germs of plague. No person who is not a commissioned medical officer, a military assistant surgeon, or a medical practitioner in possession of a qualification not lower than that of L.M.S. of the University of Calcutta, Madras or Bombay shall without the special permission of the Governor-General in Council or a local government take in his private possession from one place to another any cultures or other articles which he knows or believes to contain the living germ of plague. No such culture shall be sent from one place to another unless it is securely packed in a hermetically closed tin of adequate strength, placed in a strong outer box of wood or tin, with a layer of at least three-quarters of an inch of raw cotton wool between the inner and outer case, the outer case being enclosed in a stout cloth, securely fastened and sealed, and labelled with such distinguishing inscription as will suffice to make immediately manifest the nature of the contents.

According to a recently issued consular report, a new process for the production of ammonia has recently been discovered in Germany. The process is said to be at present an expensive one, but this difficulty will, it is thought, be overcome.

An American paper, the *Pharmaceutical Era*, has published an article by Mr. H. M. Whelpley, of St. Louis, in which particulars are given as to the use of the metric system in American physicians' prescriptions. It appears from the article that out of 1,008,500 prescriptions examined, only 6 per cent. were in the metric system. The information was obtained from apothecaries in forty-two States and territories.

A short article in the current number of the *National Geographic Magazine* sums up in brief the main results of Lieut. Peary's explorations in 1898–99, from which we extract the following information:—In the south Peary discovered that the so-called Hayes Sound, north-west of Cape Sabine, is only an inlet or bay. It was supposed by many that it extended through to the Arctic Ocean west of Ellesmere Land, and separated that country from Grinnell Land on the north. It now proved that these regions are one and the same land. He also travelled west across the northern part of Ellesmere Land, which has never before been penetrated for any distance, and visited its west coast, joining his survey of the shoreline with the short bit of the coast further north, which Lockwood, of the Greely Expedition, discovered in May 1883. This is the first time that any part of this coast has been seen south of the inlet visited by Lockwood. In his various sledge journeys up the channel from the *Windward's* position, Peary skirted the east coasts of Grinnell Land and Grant Land for a distance of about 250 miles, rectifying the mapping of this shore-line in some respects, and particularly the surveys of a number of indentations. The most northern point reached by Peary was Cape Beechey, about 82° N. latitude. No effort to push northward has been made this summer, and Peary's winter camp has been established on the Greenland side of Smith Sound, several miles further south than his quarters of a year ago.

Prof. Koch has published his first report on his study of malaria in Italy in the *Deutsche Medicinische Wochenschrift*. In all the cases of malaria examined by Prof. Koch and his assistants the parasite of malaria was found in the blood. Apart from the blood of human beings, the parasites occurred only in some species of mosquitoes which were met with only in the summer. The mosquitoes convey the malaria germs

from one human being to another: the infection is especially maintained and propagated by the relapsing cases which continue all the year round and form the link between one fever season and the next, so that the mosquitoes in the beginning of summer always find germs. If no relapse occurred in any of the cases of malaria in any given district the mosquitoes would find no germs in the beginning of summer, and malaria would become extinct there. Prof. Koch succeeded in recognising certain species of mosquitoes in the dwellings of the population; this was the more important, as the mosquitoes of this district did not usually bite during the day but only during the night. The inhabitants therefore became infected at night within their dwellings. In seven cases parasites of malaria were discovered in insects, especially in *Anopheles maculipennis*. In many dwellings, however, where patients had contracted malaria, anopheles was not present, but another insect, *Culex pipiens*, was hardly ever absent. Prof. Koch ascertained that the so-called æstivo-autumnal fevers were identical with tropical malaria.

*Industries and Iron* gives particulars of an electric fog-alarm which, it is reported, has been invented by a Canadian electrical engineer. The description is as follows:—A naphtha engine supplies the motive power to a dynamo that furnishes the electric current, by means of which three pairs of electromagnets operate half a dozen clappers that strike against a large gong with a frequency of about 36,000 strokes a minute, producing an almost continuous sound. Its effectiveness is enhanced by a mechanism somewhat on the principle of a megaphone, by means of which the sound is not only intensified but thrown in the required direction. A model of this fog-alarm was not long ago tested at Ottawa, and although it was comparatively a small affair, its sound was easily heard a distance of two miles. The sound of the completed machine will be (it is thought) distinguishable at a distance of fifteen miles.

As an example of the interest that is taken in anthropology on the continent, we call attention to the publication of the free courses of lectures delivered by Prof. E. Morselli at Turin and Genoa. The title of the publication is "Antropologia Generale: Lezioni su l'Uomo secondo la Teoria dell' Evoluzione." When will it be possible for the English public to hear systematic lectures on anthropology of any kind, free or otherwise? Prof. Morselli puts his subject clearly, judging from the portions only of the two lectures that we have received.

ANTHROPOLOGISTS who more particularly study European ethnology should be very grateful to Dr. William Z. Ripley, of Boston, for the "Selected Bibliography of the Anthropology and Ethnology of Europe" that has just been issued by the Trustees of the Public Library of Boston, Mass. The list contains nearly two thousand titles in nearly all the languages of Europe; the Slavic writers are very well represented. The authors are arranged in alphabetical order, and their several publications are cited chronologically; this is followed by a subject-index. The labour of compiling this bibliography must have been immense, but Dr. Ripley will have the satisfaction of feeling that he has supplied his colleagues with a valuable and indispensable tool.

AMONG the most useful instruments employed in Italy for the registration of earthquake movements are the microseismographs, designed by Prof. Vicentini and modified by Dr. Pacher, which have been erected in the Physical Institute of the University of Padua. Hitherto the records have been published at irregular intervals in the *Atti* of the R. Istituto Veneto di Scienze, &c., but it is now arranged that they shall appear systematically and ultimately form an appendix to the yearly volume. The first number, recently issued, contains the register from January 1 to March 12 of the present year, and also notes with regard to the arrangement of the different instruments.

THE tin trade of prehistoric Europe is a subject of considerable interest and importance. Very recently Salomon Reinach (*l'Anthropologie*, x., 1899, p. 397) has again attacked the problem and has arrived at the following conclusions. A thousand years B.C. there was an almost exclusively overland trade between the British Islands and Thrace and Macedonia. The relations between Britain, Northern Europe and Western Asia have been proved by archæology, by the diffusion of tin, amber, spiral ornaments and the types of bronze arms and utensils. Thus it is not surprising that Homeric Greece about 800 B.C. knew not only the Celtic name of the Cassiterides, but the phenomenon of the short nights of the north of Britain. The overland tin was brought to the Ægean, if not by Greeks, then by Barbarians. These Barbarians, accurately knowing the country from which the tin came, sought a marine route in order to retain this precious trade in their own hands. This was rendered more feasible by the invention of the anchor by the legendary Midas of Phrygia, for then ships could ride with safety in the open. Reinach considers that it was he who first brought tin and lead to Greece by sea by the north-west route, and it was only later that the Phœnicians got the tin trade into their hands. The English Leake, Hamilton and Ramsay have rediscovered Phrygia, but twenty-seven centuries ago the Phrygians discovered England.

THE *Bulletin de la Société Astronomique de France* for October contains several interesting meteorological articles. M. E. Touchet contributes an illustrated article on the storms of August and September 1899, showing some excellent lightning pictures. He gives special attention to the type of lightning which is apparently unaccompanied by thunder. M. A. Souleyre, writing on the "distribution of rain on the earth," summarises the interaction of the various air-currents and the barometric variations connected with rainfall. MM. V. Farquon and F. A. Mavrogordato give short accounts of their observations of the "green ray" on the Alps and at Smyrna respectively.

THE October number of the *Journal of Conchology* contains an interesting paper by Messrs. Melvill and Standen on the cowries of the *caput-serpentis* group. In that group are included not only species with a dark peripheral area and a spotted centre, like the typical *Cypraea caput-serpentis*, *C. mauritiana*, and *C. arabica*, but likewise the ring cowry (*C. annulus*) and the familiar money cowry (*C. moneta*). The two latter, as many of our readers are aware, are white; the yellow ring from which the second of the two derives its name marking the line of division between the spotted central and the dark peripheral area of the serpent-head cowry (*C. caput-serpentis*). If proof were necessary to demonstrate that this is the true explanation of the coloration of the two species, it is afforded by the discovery of a white example of a variety of *caput-serpentis*, in which the dorsal spots are still faintly visible. It has been recently stated by another writer that "from the ring cowry may easily be derived the money cowry, in which the ring has all but disappeared, while the marginal area has developed a series of rugosities, apparently connected with the filaments on the margins of the mantle lobes." And Messrs. Melville and Standen now come to the conclusion that these two cowries are really nothing more than races of a single species, for which the name *C. moneta* should be retained.

THE last number of the *Transactions* of the Norfolk and Norwich Naturalists' Society bears ample testimony to the maintenance of the taste for natural history and botany which has always been so characteristic of that favoured county. As is only proper, the great bulk of the papers refer to local

subjects, while a few, like Mr. Warde Fowler's notes on the birds of the Somme Valley, supplement the history of native species in other lands, the remainder having no particular connection with the county. Especial interest attaches to Mr. S. F. Harmer's note on the occurrence of the well-shrimp (*Niphargus*) near Norwich; and likewise to Mr. J. H. Gurney's account of the distribution of the Bearded Tit. Various specialists bring the lists of the Norfolk fauna and flora up to date. And those who study economic zoology will be interested in the notes of Mr. G. H. Harris on the herring fishery of 1898. So far as the Yarmouth boats were concerned, this appears to have been a practical failure. It was not that the catch was always bad; but, whatever the catch, prices were forced down by the poor quality of the fish. And this is mainly attributed to the mild season, herrings being never of high quality in warm weather.

AMONG recent papers in the *Journal of Applied Microscopy*, Mr. Charles J. Chamberlain's series of articles on "Methods in Plant Histology" will be useful to teachers and students of practical botany. The last articles contain illustrated accounts of the principal families of algæ with methods of preparing for observation. One of these methods is, however, capable of improvement. To place specimens in a 10 per cent. solution of glycerine, and allow the solution to evaporate till it is of the consistency of pure glycerine would be unnecessarily tedious. It is simpler and equally efficacious to place the specimens in water in a small receptacle of parchment paper, and float the latter on glycerine, the change of density taking place through the paper by osmosis instead of by evaporation.

A VERY clear photographic group of official members of the recent Dover meeting of the British Association, together with members of the French Association and the Belgian Geological Society, has been sent to us by the photographers, Messrs. Lambert Weston and Sons, of Dover, from whom copies may be obtained. In the majority of instances the individuals portrayed can easily be identified.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus*, ♀) from India, presented by Mrs. J. Adams; a Black-faced Spider Monkey (*Ateles ater*) from Eastern Peru, presented by Mr. Claude P. Landi; a Common Chameleon (*Chamaeleon vulgaris*) from North Africa, presented by Mr. A. H. Ryan; a Red-cheeked Souslik (*Spermophilus erythrogenys*), four Eversmann's Sousliks (*Spermophilus altaicus*), four Altai Sousliks (*Spermophilus mugosaricus*) from Western Siberia, a Common Seal (*Phoca vitulina*), British, a Common Cormorant (*Phalacrocorax carbo*, var.), European, an Emu (*Dromaeus novae-hollandiae*), three Long-necked Chelodines (*Chelodina longicollis*) from Australia, an Uvæan Parrakeet (*Nymphicus uvaeensis*) from the Island of Uvea, a Rosy Parrakeet (*Palaeornis rosa*) from Burmah, a Four-lined Tree-frog (*Polypedates quadrilineatus*) from the East Indies, a Westerman's Eclectus (*Eclectus westermani*) from Moluccas, deposited; six Glossy Ibises (*Plegadis falcinellus*), bred in the Gardens.

## OUR ASTRONOMICAL COLUMN.

COMET GIACOBINI (1899 *e*).

*Ephemeris for* 12*h*. *Berlin Mean Time*.

| 1899. | R.A. h. m. s. | Decl. ° ′ | Br. |
|---|---|---|---|
| Oct. 19 | 16 57 8 | +0 46·4 | |
| 21 | 17 0 3 | 1 19·0 | 0·71 |
| 23 | 2 59 | 1 51·2 | |
| 25 | 5 55 | 2 23·0 | 0·66 |
| 27 | 8 52 | 2 54·5 | |
| 29 | 17 11 49 | +3 25·6 | 0·62 |

A circular from the Centralstelle at Kiel informs us that owing to an error in one of the published observations, there is some doubt as to the correct elements of this comet. In consequence of this the above ephemeris may not be quite accurate, but, as according to the latest observation recorded, it is less than one minute in R.A. and two minutes in Decl. in error, it will be useful for searching purposes. The comet is travelling to the north-east through Ophiuchus, a little south of the second mag. star α Ophiuchi.

HOLMES' COMET (1899 *d*).

*Ephemeris for* 12*h*. *Greenwich Mean Time*.

| 1899. | R.A. h. m. s. | Decl. ° ′ ″ |
|---|---|---|
| Oct. 19 | 2 53 1 | +48 49 51 |
| 20 | 51 57 | 48 54 5 |
| 21 | 50 51 | 48 57 56 |
| 22 | 49 44 | 49 1 25 |
| 23 | 48 36 | 49 4 30 |
| 24 | 47 27 | 49 7 13 |
| 25 | 46 17 | 49 9 33 |
| 26 | 2 45 7 | +49 11 29 |

This comet is now in the middle of Perseus, being nearly on the line joining β and γ Persei, about two-thirds of their distance from the former.

OPPOSITION OF JUPITER, 1899.—*Astronomische Nachrichten* (Bd. 150, No. 3596) contains the results of several observers' work on the planet during the last opposition of 1899 April 25. M. J. Comas Solá, of the Catala Observatory, gives a planispheric map of the markings observed by him with a Mailhat objective of 22 cm. aperture, from February 18 to July 8. Tables are given showing the various rotation periods obtained from observations of spots in different zones, a summary of which is as follows:—

Mean velocity of spots on south border of equatorial zone ... } = 9h. 50m. 23·35s. (from 22 spots)
Mean velocity of spots on north border of equatorial zone ... } = 9h. 50m. 15·25s. (from 9 spots)
∴ mean equatorial velocity ... = 9h. 50m. 20·76s.

This, compared with Denning's mean velocity for 1898, 9h. 50m. 23·6s., would indicate an acceleration since the spring of 1897.

Measures of the "red spot" gave a period of 9h. 55m. 41·85s.

Herr Ph. Fauth also gives a planispheric drawing showing the details observed from May 30 to June 13, with a Pauly objective of 17·8 cm. aperture.

Mr. A. Stanley Williams, of Brighton, gives his observations of the "red spot" made during the period March 13 to June 16 with a 6½-inch reflector. The period found is given as 9h. 55m. 42·65s. from 229 rotations (March 13 to June 16). He finds the spot to be a little shorter now than it was in 1887 (31°·7 instead of 34°·7).

LAW CONNECTING MOTIONS IN PLANETARY SYSTEM.—M. Ch. V. Zenger, of Prague, has recently put forward the results of work he has been engaged on for some years past, and a part dealing with the relations existing between the "time of a planet's revolution" and its position in the solar system appears in the *Bulletin de la Soc. Ast. de France*, October 1899, pp. 431–434. He finds that the orbital movements of the planets and also of some periodical comets have a simple law connecting them with the time of the sun's rotation. If "*r*" is the time of *rotation* of the central controlling body, then "R," the time of *orbital revolution* of the planet, is given by the relation $R = n\frac{r}{2}$; where "*n*" is a whole integer, different for each body.

Taking Faye's value for the solar rotation = 25·2 days, $\frac{r}{2}$ = 12·6 days, and the author gives the following data:—

| | Mercury | Venus | Earth | Eros | Mars | Jupiter | Saturn | Uranus | Neptune |
|---|---|---|---|---|---|---|---|---|---|
| N = | 7 | 18 | 29 | 51 | 54 | 344 | 854 | 2436 | 4776 |
| R | 88·2d. | 226·8d. | 365·4 | 642·6 | 680·4 | 4344·4 | 10765·4 | 30693·6 | 60177·6. |

Between the earth and Eros, the author mentions the possible existence of a hitherto unknown planet for which $n = 40$, and the period of revolution of which would therefore be about 500·4 days.

Several tables are also given showing the conformation of the satellites of the various planets to a similar relation, and the author considers the whole as helping to confirm his electrical theory of the solar system.

## *ON THE CHARACTERISTICS OF A UNIVERSITY.*

THE beginning of a new academical year is one of those periods of sudden change which must leave its mark for good or bad on every university and college in the land. Well-known faces of those who have been prominent in work or sport are missing. New recruits are taking, with halting steps, their first lessons in the drill which is soon to become so familiar. In a few days they will be undergoing their "baptism of fire" in struggles wider and keener than any in which they have yet been engaged; and in which each, according as he bears himself, must either add to or diminish, be it by ever so little, the position which his college holds in the eyes of the world. At such a period we naturally halt for a moment, and before we face the future, cast our eyes backward.

One conspicuous change has taken place in the past session. Sir John Donnelly has retired from the permanent headship of the Department of Science and Art, and has been replaced under new conditions by Captain Abney. It would be contrary to all the wholesome traditions which govern the conduct of servants of the Crown if I attempted to discuss these important events. I will therefore only say, in words which are colder than my feelings, that we wish our late chief long life, health and happiness in the rest to which the strenuous service of many years has entitled him; and that we welcome as his successor one who is not only a distinguished public servant, but a distinguished man of science.

Two losses, I must mention, of men who, though unknown to each other, were both known to many of us. Both had, in different ways, deserved well of the college. Both have passed away since the last term ended. But though alike in these respects, their fates were strangely different.

Sir Edward Frankland, for long Professor of Chemistry in this college, had touched the topmost rungs of the ladder of scientific fame. The Royal Society bestowed upon him its highest honour—the Copley Medal. The French Academy of Sciences had given him the highest distinction it can confer upon one who is not a Frenchman, by placing his name on the select list of eight foreign members. Happy in the work of his life, he was no less happy in the opportunity of death. The end came, without long previous suffering or slackening of mental power, in the midst of the holiday haunts which must, as life faded, have recalled some of its brightest hours. The Royal College of Science will remember him as one of the earliest and the most distinguished members of its staff.

The other name I would mention is that of one who was recently numbered among our students. Ernest Harrison gained the Associateship in Physics a year ago, taking the first place in the final examination. He had previously won a scholarship at Trinity College, Cambridge. His career here gave reason to believe that his future would be successful; but his early death has quenched the hopes of his teachers and his friends. The fact that he has died a very young and therefore a comparatively unknown man, makes it all the more the sad duty of us who knew him to record the promise of his youth.

Turning from the past, the changes which loom largest in the immediate future are the erection of the new buildings and the creation of what will in effect be a new university. Of the former I will only say that they will be on a scale not unworthy of the largest city in the world; but the establishment of a teaching university must be so pregnant with good or ill that I shall offer no apology for returning, by a somewhat different line of approach, to a subject on which Sir Norman Lockyer dwelt last year.

Let us then, in the first place, ask what are the chief notes which distinguish from all others the mode of preparation for the work of life which should be characteristic of a university.

Put shortly, I take it that two notes are predominant above all the rest. The first is that a university is a place where education is combined with the advancement of knowledge; the second, that the teaching of a university is based upon the principle that knowledge is desirable for the influence which knowledge and the search for knowledge exert upon ourselves, and not merely for the power which they confer of improving our external surroundings. The first of these characteristics distinguishes the university from a school; the second from a workshop or a college with purely technical aims.

[1] [illegible] delivered at the opening of the Royal College of Science, [illegible] by Prof. Rucker, F.R.S.

I shall say very little on the fact, which no one will dispute, that it is the duty of a university to advance knowledge. To do us justice, we of the Royal College of Science have not been unmindful of this duty. It is impossible to speak of the present or more recent past, but I may be permitted to say that a college which has numbered Huxley, Stokes and Frankland among the members of its staff will have forgotten all the teaching of its earlier history if it ever fails to satisfy the first test of fitness for a university status. I only hope that the schemes which are being mooted for founding new research professorships do not veil an attempt to place in other hands that part of the work of the London colleges which is specially characteristic of a university. London needs a multiplication of teachers on a sufficiently large scale to enable them to conduct both teaching and research, not the creation of separate castes of teachers and investigators.

Let me turn next to the second note of a university, viz. that it insists that knowledge has a value apart from the commercial or utilitarian objects for which it may be used.

In this capacity a university maintains, or ought to maintain, a constant protest against the view that a man and his knowledge are to be measured by their money value alone. This view was never more clearly expressed than by Colonel Diver, according to whom the aristocracy of New York consisted "of intelligence, sir, . . . of intelligence and virtue. And of their necessary consequence in this republic—dollars, sir." It is needless to deny that "dollars" are often the reward o. intelligence and virtue. In the case of most men, the search after them must necessarily be a matter of importance; but this fact is too often used to make preparation for the business side of life the only or the chief end of education.

As I was writing these lines a number of *Literature* reached me, in which there is a review of a work by an assistant professor of the history and art of teaching in the Harvard University. This gentleman proposes to have "commercial courses" in all the schools. The purpose of these courses is to be, not merely "to train a youth to an appreciation of the functions of business and business practice in our modern life," and not merely to "inform him as to the history of industry and trade," but also to "awaken in him a profound interest in business as such," and to "train him to keep his eyes open to business possibilities."

Before I have done you will understand my reasons for agreeing with the reviewer that this is a "hideous educational programme." For the moment I will content myself with saying that it is based upon a one-sided view of life. There can be no question but that the business element is important, but a university is a corrective to the tendency to regard money as the only standard of value. This it does by inviting us to study and to care for things which we must admit are important and beautiful, but which we may not be able to convert into coin.

But, you may ask, if this is so, will not the admission o. technical colleges such as is, in part, our own, be inconsistent with your idea of a university?

To this I answer that, while it is possible that the desire to master the practical applications of knowledge might crush the desire to know things which are worthy to be known though not of immediate commercial advantage, the men who are managing the best technical colleges are aiming at leavening the technicalities of a profession with the love of knowledge. Example will illustrate what I mean better than precept. The late Dr. Hopkinson was a successful engineer, sought after to superintend great undertakings. Busy in the office and the law courts, he nevertheless was always investigating the secrets of nature, and wrote his name large in the *Transactions* of the Royal Society. Many others, whom in this room I need not mention, are animated by the same spirit. I think, therefore, that the welcome which several of our universities have extended and are extending to such men and to their students is a legitimate recognition of the fact that they have effected a real extension of the boundaries of the region in which the love of knowledge for its own sake prevails. It would be a disaster if the spirit of business and commerce were to dominate a university. It will be a triumph if the love of science and the love of culture were spread from the technical college to the machine shop and the factory.

And this brings me to my next point, to another and more subtle question, in some respects similar to that we have been discussing.

In life there is a competition, not merely between commercial

and intellectual interests, but between different intellectual interests themselves; and a characteristic of a university education is that by some means or other it aims at conveying, not merely accurate knowledge on some one subject, but a healthy interest in all forms of mental effort. This wider range, this general cultivation, should distinguish the university scholar from him who has merely mastered the technicalities of a profession. A man may be a good lawyer or tradesman, he may have grasped a branch of pure science or succeeded in a scientific profession, and yet be careless and ignorant of all that does not bear upon the central interest of his life. The blending of expert and general knowledge, of professional skill in some one subject and of intelligent interest in others, is not to be accomplished by obeying formal rules, such as those which must be followed in producing a given chemical compound. Each one of us must decide for himself what particular combination represents for him the maximum of gain and the minimum of loss; but the true university as distinguished from the professional or technical school is for ever preaching that man is many-sided, that the light of heaven reaches him through many windows, and though to some of us the call may come to sacrifice all else to gain one supreme end, yet it is well to count the cost and to remember that the loss may outweigh the gain.

In speaking of sacrifice I am not now referring to the ordinary habits of industry and self-control which are essential to success in any physical or intellectual struggle. I am dealing rather with that sacrifice which is so often made without any sense of loss, the surrender of all effort to understand the appeal made by nature or art to one or other of our higher intellectual powers.

A man may be so interested in painting or in music that he loses all sense of the divine curiosity which impels the man of science as he strives to unravel the plan of the universe. The seeker after truth may allow the dry light of science to wither the sensibilities which can be touched by art alone. He may purchase the higher knowledge at the cost of the higher emotions.

Let us then consider for a few moments the principles which should direct our choice, and the help which a University of London can give us in choosing.

With regard to principles, it is impossible, as I have already said, to lay down any hard and fast rules. In this, as in so many other questions on which a practical decision must be made, two extreme courses are possible to follow, either of which is in most cases clearly wrong. I shall call before you a distinguished advocate of each, and allow them to plead in their own words.

The first policy may be called the policy of concentration, dear to the apostles of the gospel of self-help.

"The one prudence in life," says Emerson in his essay on Power, "the one prudence in life is concentration; the one evil is dissipation: and it makes no difference whether our dissipations are coarse or fine; property and its cares, friends, and a social habit, or politics, or music, or feasting. Everything is good which takes away one plaything and delusion more, and drives us home to add one stroke of faithful work. Friends, books, pictures, lower duties, talents, flatteries, hopes—all are distractions which cause oscillations in our giddy balloon, and make a good poise and a straight course impossible. You must elect your work; you shall take what your brain can, and drop all the rest. Only so can that amount of vital force accumulate which can make the step from knowing to doing. . . 'Tis a step out of a chalk circle of imbecility into fruitfulness."

And yet what counsel is this! To you the happiness or sorrows of your friends are to be mere distractions which make a straight course towards the conclusion of your own task impossible. Politics—that is the well-being of your country; books, the whole world of literature; music and pictures, all these are mere playthings and delusions, which you are to cast aside with all other childish things, and now that you are a man you are to care only for doing your own stroke of faithful work.

It is nothing to you that you are viewing with callous indifference the faithful work of others. "At sundry times and in divers manners" the noblest of our race have been striving to express the best that was in them by poetry and prose, by line and colour, by oratory and music. You are to care for none of these things. They are dissipations—not indeed of the coarsest kind—but dissipations none the less, dissipations which distract you from your own sustained and self-conscious endeavour to do something which may perhaps entitle you to rank among the meanest of those whose works you spurn. And then, when the work is done, the discovery made, the memoir published, what wonder if they in turn regard it with a disdain not less than your own? what wonder if Charles Lamb, along with Court Calendars, Directories, Draught Boards, bound and lettered on the back, and Almanacs, should place scientific treatises in his list of Biblia A-Biblia; or Books which are not Books?

Turn now to the other extreme policy, that which regards it as our wisdom to aim, not so much at one high end which can be attained only by an intense concentration, as at the "fruit of a quickened, multiplied consciousness."

No one has put the case in support of this philosophy more eloquently than Walter Pater in the celebrated conclusion to his "Studies in the History of the Renaissance."

The passage is too long to quote in full, but he tells us that the service of culture to the human spirit "is to startle it into a sharp and eager observation.

"Every moment some form grows perfect in hand or face; some tone on the hills or sea is choicer than the rest; some mood of passion or insight or intellectual excitement is irresistibly real or attractive for us—for that moment only.

"Not the fruit of experience, but experience itself is the end. A counted number of pulses only is given to us of a variegated, dramatic life. How may we see in them all that is to be seen by the finest senses? How can we pass most swiftly from point to point, and be present always at the focus where the greatest number of vital forces unite in their purest energy?

"To burn always with this hard gem-like flame, to maintain this ecstasy, is success in life. Failure is to form habits: for habit is relative to a stereotyped world; meantime it is only the roughness of the eye that makes any two persons, things, situations, seem alike.

"While all melts under our feet, we may well catch at any exquisite passion, or any contribution to knowledge, that seems by a lifted horizon to set the spirit free for a moment, or any stirring of the senses, strange dyes, strange flowers, and curious odours, or work of the artist's hands, or the face of one's friend.

"Not to discriminate every moment some passionate attitude in those about us, and in the brilliance of their gifts some tragic dividing of forces on their ways, is, on this short day of frost and sun, to sleep before evening."

Beautiful words! But as their music fades from the ear, as the brilliance of the "hard, gem-like flame" is quenched by the light of day, can we accept their teaching? Not to do but to feel, not to achieve but to enjoy, is the rule of life to be deduced logically from these premisses. If some great work is to be attempted, it is for the sake of the experience, for the joy of the effort and the success, and not for the sake of the work itself. Even "the enthusiasm of humanity" is classed by Pater among the "high passions," which are valuable chiefly for "the quickened sense of life" they impart; and beyond and above them all is placed art, not because it leads to a noble end, but because it professes "to give nothing but the highest quality to your moments as they pass, and simply for those moments' sake."

If the doctrine of concentration leads to ignorance of the work of others, the doctrine of the multiplication of states of consciousness leads to the neglect of what you yourself may do. Nay, more; it leads to the paradoxical result that you laud and magnify the achievements of those whom, nevertheless, you count as having failed in life, if their work, like most of the best work of the world, has been brought to the birth with bitter travail; and if, in the effort to achieve, they have sacrificed the joys to be found in "strange dyes, strange flowers, and curious odours."

If you have to choose one philosophy or the other, to adopt one rigid rule of life, I take it that the nobler among you would follow Emerson rather than Pater, would prefer to do "one stroke of faithful work" rather than to maintain a life long ecstasy. But this is not one of the cases in which no compromise is possible, in which we must vote "Yea" or "Nay," and must put aside wholly one teaching or the other. It may be a great thing to make the efforts and sacrifices which are required in adopting an extreme position, but it is a still higher achievement to maintain through life the intellectual balance necessary for the policy of the "golden mean."

I am not concerned to deny that radically different views

underlay the teaching of Emerson and Pater, but nothing is more certain than that neither Emerson nor Pater meant the passages I have read to be taken in the literal sense which might be ascribed to them. Even in the teaching of science it is sometimes necessary for the teacher to aim at being clear rather than correct; to force home the appreciation of the nature of some central truth by stating it as boldly as possible, and by sacrificing the pedantic exactitude which would insist that in its very first presentment it must be hedged about with every qualification and safeguard which long experience could suggest.

This was not the policy of the American teacher. Having set the mind in motion he left to its natural "after working" the discovery of qualifications and safeguards.

"Emerson," says Mr. John Morley, "has not worked out his answers to these eternal enigmas, for ever reproducing themselves in all ages, in such a form as to defy the logician's challenge. He never shrinks from inconsistent propositions. He was unsystematic on principle. 'He thought that truth has so many facets that the best we can do is to notice each in turn, without troubling ourselves whether they agree.'"

No better evidence of the truth of this remark could be adduced than Emerson's treatment of the relative importance of special knowledge and general culture. We have heard him on the one side. Let us listen to what he has to say on the other.

"He only is a well-made man who has a good determination. And the end of culture is not to destroy this. God forbid! but to train away all impediment and mixture, and leave nothing but pure power. Our student must have a style and determination, and be a master in his own specialty. But, having this, he must put it behind him. He must have a catholicity, a power to see with a free and disengaged look every object."

Nor by putting "behind him" did Emerson mean that the student was to devote all his earlier years to one form of intellectual effort: and that when this had brought him competence or fame, he might turn for relaxation to what he had hitherto neglected—to art or science or literature, as the case might be.

"Culture," he says elsewhere, "cannot begin too early. In talking with scholars I observe that they lost on ruder companions those years of boyhood which alone could give imaginative literature a religious and infinite quality in their esteem."

He who has pored too closely and too long over one study cannot in a moment cast aside the fetters which the years have woven round him, and rise up, like Samson, a terror to the Philistines. The intellectual sectarian cannot by a sudden act of will or process of conversion become the intellectual catholic. As well might he hope that the muscles which have been disused for years should suddenly rival the sturdy frame of the athlete, that the bent back should become straight, and the vision of the wearied eyes keen. Mental, like physical powers, are atrophied by disuse. The arts of seeing something of many things and all of one must be cultivated at the same time, or side by side.

And Pater, like Emerson, trusted to the intelligence of the reader not to mistake the strong presentment of one side of a question for a judicial decision on the whole case. So shocked was he when it was pointed out to him that his teaching might be taken too literally, that he actually suppressed the magnificent passages I have read to you lest his meaning should be misunderstood.

For each of us, then, the safest path lies somewhere between these limits, though thousands lead dull or unsuccessful lives because they shape their course perilously near to one or other of them. My object to-day is to warn you against the two extremes, not to attempt to lay down rules which shall point out the best course between them, rules which could not serve for all characters and dispositions alike. Do not forget that nothing considerable is achieved without concentration. Remember that he who holds himself free to cast aside every interest which does not directly bear on the central object of his life purchases this freedom "with a great price."

Let us next inquire what a university can do to guide the student in his choice. And here I may say at once that in my opinion the methods which have been officially adopted have been open to grave criticism; and that even if this were not so, the secondary are at least as important as the primary effects of a university training.

The direct official method of promoting general knowledge has been to insist that the candidate must pass an examination in several diverse subjects either before or during his passage through the university.

No objection can be raised to regulations which insist that a student before entering the university shall have acquired the elementary knowledge and have undergone the intellectual training which may enable him to undertake more difficult studies; but cultivation is not attained by mastering Latin and Greek up to the point at which they become useful engines for cultivation, and then throwing them aside for life. To change the metaphor, studies so treated are, in the words of Mr. John Morley, "superfluous roots in the mind, which are only planted that they may be presently cast out again with infinite distraction and waste."

Mistakes such as these are due to the fact that, though each subject of study when regarded as central is surrounded by others which are very different from itself, but which nevertheless prop and support it, these subsidiary subjects are (as a rule) not officially recognised in the examinations for a degree.

Every scientific man would agree that a student who can read French and German is better prepared for a scientific career than one who, with an equal knowledge of science, can read English only. Why not allow to the higher attainments greater weight? Again, there can be no doubt that a scientific essay or treatise written in good English tends more to the advancement of "natural knowledge" than if the facts and arguments are badly expressed. Why not recognise this fact, as the Department of Science and Art has now done, by giving credit in the Honour examinations for the style in which the essays of candidates are written?

By such steps we should, at all events, secure that the teacher of science who chooses to take some pains with the essays of his students, or who urges them to learn to read French and German easily, should not feel that his advice, however useful it might ultimately be, would damage rather than improve their chances of a high place in the examination for a degree in science. Thus, too, we should keep open in the student's mind avenues by which he might attain to some interest in language and literature for their own sakes.

I am well aware of the objections which might be raised to such a scheme; and though I do not myself attach great weight to them, I will now only insist that if they are valid that fact is an additional proof of the truth of a proposition, which I do not deny, viz. that it is not so much by directing the studies of each individual student, as by bringing together teachers and learners who are teaching and learning very different things, that, by a mental "law of exchanges," the interests of all are widened.

It is no doubt a weak point in a college such as ours that the range of instruction is limited to science and to some of its applications, and that thus you are all studying closely allied subjects. Union with other colleges in a university may help to remedy this defect. Meanwhile, all that can be done officially to promote general cultivation is small compared with what you can do for yourselves and for each other, and this because you are at liberty to embrace a wider range than any university would be justified in forcing upon you. Your success as specialists will largely depend upon your studies and your teachers. Your wider cultivation will chiefly be the work of your relaxations and your friends.

Do not misunderstand me. In general, a young man with no physical defect will and ought to take an interest and a part in athletics. In a great metropolis this is even more necessary than in the case of universities which, like Oxford, Cambridge, St. Andrews or Gottingen, are comparatively in the country.

I am proud to be the president of a Boat Club which this summer won a race in a Thames regatta. I have been treasurer of two scientific societies, and am glad to be now the treasurer of the United Football Clubs of the engineering departments of the London Colleges. I hope and believe that these are the germs from which the athletic clubs of the future university will spring. I hope and believe that the undergraduates of that university will not differ from all other groups of young Englishmen in that, while engaged in the cultivation of intellect and taste, they neglect the cultivation of thews and sinews. But if it be granted that college work and college sports must fill up much of the time of all of you, there are still spare but precious moments in which you cannot indeed master, but may ward off, complete ignorance of things which have little to do with your studies or your sports, but are none the less worth knowing and loving. You have college societies where such things are discussed

and debated. They are described in the excellent little pamphlet which has been put in every freshman's hand. You can at the least do what is in your power to attend and support them. You can take care that your undergraduate days do not pass without the great names of literature becoming more than names to you. Books can be had for the asking from public libraries, they can be bought for pence where they used to cost shillings. We owe to the generosity of Prof. Perry the nucleus of a college library containing books which are not scientific. He who now devotes to literary trash time which he might spend in learning something of one of the greatest literatures of the world has nobody but himself to thank if his reading vulgarises instead of refines him. Taste is educated only by tasting; and it rests with yourselves whether you will learn to appreciate the difference between the great masters of the pen and penny-a-liners, between the wit of a great humourist and the vulgarities of the funny corner of a second-rate newspaper.

A bicycle ride will be none the less enjoyable if you train yourself, not merely to travel far, but to take an interest in the sights and scenes through which you pass. For the sake of example, let me remind you that no country is so rich as England in the architecture of its village churches. It is no hard matter to learn to recognise the principal peculiarities of the architectural types which prevailed from the days of the Saxons to Sir Christopher Wren. The text-books are, I presume, to be found in the Art Library. But as soon as the elements of English church architecture are known, an old church ceases to be merely a picturesque object. It is an historical document which you yourself can read. You do not need the aid of the sexton to tell you which is the oldest part. You can make a good guess at when that aisle was added, or that window knocked in a wall obviously older than itself. A visit to a cathedral becomes an intellectual pleasure. Weariness at the drone of the verger as he recites his oft-repeated lesson is replaced by an alert desire to know if the authorities from whom he learnt it confirm or correct the rapid conclusions as to date or history to which you yourself have come.

I might multiply such examples. Nowhere in England can you so easily or so cheaply as in London hear and learn to appreciate the best music the world has produced.

The wet half holidays of an undergraduate's career well spent in the National Gallery would give you a familiarity with all the great schools of painting which few travellers attain.

Every day as you come to or leave your work you may pass through one of the greatest art collections in the world, and it depends upon you alone as to whether you shall or shall not learn anything from it.

Understand me clearly when I reiterate that I am laying down no rules. I have tried only to lay the problem before you. How to combine the proper care for pounds, shillings, and pence with the love of knowledge for its own sake; how best to balance your various studies; how to add to the concentration required for the mastery of a single subject the open eye and the refined taste which may lead you to appreciate arts which you cannot emulate, and things beautiful which you can neither copy nor produce; these are problems in which a university may help you, but can help you only if you are willing to help yourselves. I have to-day aimed at nothing more than at reminding you that each one of the mental forces we have discussed is essential to the equilibrium of intellectual life; that if you wilfully neglect any of them, or devote yourselves too exclusively to one, you will fall short, and, it may be, sadly short, of the ideal which the true university holds up to her sons.

## FORTHCOMING BOOKS OF SCIENCE.

MR. EDWARD ARNOLD'S list includes:—"Dynamics for Engineering Students," by Prof. W. E. Dalby; "Physical Calculus," by Percy E. Bateman; "Text-book of Physical Chemistry," by Dr. R. A. Lehfeldt; "A Manual of Elementary Chemistry," by W. A. Shenstone, F.R.S.; "Magnetism and Electricity," by J. Paley Yorke; "A Manual of Botany," by David Houston; "A Manual of Physiography," by Dr. Andrew J. Herbertson; "A Text-book of Domestic Science," by Mrs. S. J. Shaw; "Elementary Natural Philosophy," by Alfred Earl; "Wood: its Natural History and Industrial Applications," by Prof. G. S. Boulger; "The Dressing of Minerals," by Prof. Henry Louis; and a new edition of "Animal Life and Intelligence," by Prof. C. Lloyd Morgan, F.R.S.

The list of Messrs. Baillière, Tindall, and Cox contains:—"Dictionary of French-English Medical Terms," by H. De Méric; "The X-ray Case-book for Noting Apparatus, Methods and Results, with Full Diagrams of the Human Body," by Dr. D. Walsh; "The Pathological Statistics of Insanity," by Francis O. Simpson; "Difficult Digestion due to Displacements," by Dr. A. Symons Eccles; "An Introduction to the Diseases of the Nervous System," by Dr. H. Campbell Thomson; "A Manual for Nurses," by Florence Haig-Brown "The Artistic Anatomy of the Horse," by Dr. U. W. Armstead, illustrated; "Statistics of Food Adulteration and Suggested Standards," by C. G. Moor and C. H. Cribb; and new editions of "A Synopsis of the British Pharmacopœia, 1898," compiled by H. Wippell Gadd, with Analytical Notes and Suggested Standards, by C. G. Moor. "Practical Guide to the Public Health Acts. A Vade Mecum for Officers of Health and Inspectors of Nuisances," by Dr. T. Whiteside Hime; "Manual of Surgery for Students and Practitioners," by Drs. W. Rose and A. Carless; "Heart Disease, with Special Reference to Prognosis and Treatment," by Sir W. H. Broadbent, Bart, M.D., F.R.S., and Dr. J. F. H. Broadbent; "Practical Horse-Shoeing," by Dr. George Fleming.

In Messrs. G. Bell and Sons' list we find:—"Comparative Physiology," by G. C. Bourne; "Physiography," by H. N. Dickson; "Chemistry," by Prof. James Walker; "Mechanics," by Prof. G. M. Minchin, F.R.S.; "Electricity and Magnetism," by Prof. Oliver J. Lodge, F.R.S.; "Elementary General Science," by D. E. Jones and D. S. McNair. "A Short Course of Elementary Plane Trigonometry," by Charles Pendlebury.

In Messrs. A. and C. Black's list are:—"Newton's Laws of Motion," by Prof. P. G. Tait; "A Text-Book of Zoology," by Prof. E. Ray Lankester, F.R.S.

The list of Messrs. Blackie and Son, Ltd., includes:—"Among the Birds in Northern Shires," by Charles Dixon; "A Book of Birds," by Carton Moore Park, illustrated.

Messrs. W. Blackwood and Sons promise:—"Practical Nursing," by Isla Stewart and Dr. Herbert E. Cuff; "Physical Maps for the Use of History Students," by Bernhard V. Darbishire; "A Manual of Classical Geography," by John L. Myres; "Exercises in Geometry," by J. A. Third.

Messrs. Gebrüder Borntraeger (Berlin) will publish:—"Eine Landschaft der Steinkohlen-Zeit," by Dr. H. Potonié.

Mr. T. Burleigh announces:—"Our Common Cuckoos, other Cuckoos and Parasitical Birds," by Dr. Alexander Japp.

The announcements of the Cambridge University Press include:—"Scientific Papers," by Prof. P. G. Tait, vol. ii; "The Scientific Papers of John Couch Adams," vol. ii, edited by Prof. W. G. Adams, F.R.S., and R. A. Sampson; "Scientific Papers," by Lord Rayleigh, F.R.S.; "Scientific Papers," by the late Dr. John Hopkinson, F.R.S., in 2 vols.; "Scientific Papers," by Prof. Osborne Reynolds, F.R.S.; "Aether and Matter," a development of the relations of the aether to material media, including a discussion of the influence of the earth's motion on the phenomena of light; being one of two essays to which the Adams prize was adjudged in 1899 in the University of Cambridge, by Dr. Joseph Larmor, F.R.S.; "Aberration," a study of the relations between the ether and matter: being one of two essays to which the Adams prize was adjudged in 1899 in the University of Cambridge, by G. T. Walker; "The Theory of Differential Equations," part ii., ordinary equations, not linear, by Prof. A. R. Forsyth, F.R.S., in 2 vols.; "The Strength of Materials," by Prof. J. A. Ewing, F.R.S.; "A Treatise on the Theory of Screws," by Prof. Sir Robert S. Ball, F.R.S.; "A Treatise on Geometrical Optics," by R. A. Herman; "Zoological Results based on material from New Britain, New Guinea, Loyalty Islands and elsewhere, collected during the years 1895, 1896 and 1897, by Dr. Arthur Willey, part iv., illustrated; "Fauna Hawaiiensis, or the Zoology of the Sandwich Islands," being results of the explorations instituted by the joint committee appointed by the Royal Society of London for promoting natural knowledge and the British Association for the Advancement of Science, and carried on with the assistance of those bodies and of the Trustees of the Bernice Pauahi Bishop Museum, edited by Dr. David Sharp, F.R.S.; vol. ii., part i., Orthoptera, by R. C. L. Perkins; vol. ii., part ii., Neuroptera, by R. C. L. Perkins; "Fossil Plants," by A. C. Seward, F.R.S., vol. ii.; "Electricity and Magnetism," by R. T. Glazebrook, F.R.S.; "Crystallography," by Prof. W. J. Lewis; "Military

Geography," by Dr. T. M. Maguire; "The Teaching of Geography in Switzerland and North Italy," by J. B. Reynolds; "Educational Aims and Methods," lectures and addresses by Sir Joshua Fitch; "The Teacher's Manual of School Hygiene," by Dr. E. W. Hope and E. Browne; "A New Primer of Astronomy," by Prof. Sir Robert S. Ball, F.R.S; "A New Primer of Mechanics," by L. R. Wilberforce; "A New Primer of Physics," by the same author; "A New Primer of Chemistry," by F. H. Neville: "A New Primer of Physiology," by Dr. Alex. Hill; "A Brief History of Geographical Discovery since 1400," by Dr. F. H. H. Guillemard: "An Introduction to Physiography," by W. N. Shaw; "Euclid. Books I–III with simple exercises," by R. T. Wright; "Geometrical Drawing," by W. H. Blythe.

Messrs Cassell and Co.'s list contains:—"Our Rarer British Breeding Birds, their Nests, Eggs and Breeding Haunts," by Richard Kearton, illustrated; "Familiar Wild Flowers," by F. E. Hulme, new vol., illustrated; "A Practical Method of Teaching Geography," by J. H. Overton, vol. ii.; and a new edition of "Starland," by Prof. Sir R. S. Ball, F.R.S.

Messrs. W. and R. Chambers will publish:—"Commercial Geography," by Dr. A. J. Herbertson.

Among the books in preparation at the Clarendon Press may be mentioned:—"Physical Aspects of Soils," by Prof. Robert Warington, F.R.S.; "A Catalogue of Eastern Lepidoptera Heterocera in the Oxford University Museum," by Colonel C. Swinhoe (Part II., Noctuina); Authorised Translations of Pfeffer's "Pflanzenphysiologie," by Dr. A. G. Ewart, and Goebel's "Pflanzenorganographie," by Prof. I. Bayley Balfour, F.R.S.

The Columbus Company, Ltd., promise:—"A Series of Servian Folk-lore Stories," by Elodie L. Mijatovich.

Messrs. Archibald Constable and Co. give notice of:—"Art Enamelling upon Metals," by H. H. Cunynghame, illustrated; "Auto-Cars and Horseless Carriages," by Dugald Clerk and Worby Beaumont, illustrated; "Acetylene Gas," by Prof. Vivian B. Lewes, illustrated; "The Simplest Living Things," by Prof. E. Ray Lankester, F.R.S.; "The Victoria History of the Counties of England: Hampshire," in which the various branches of Science will be dealt with by specialists.

Messrs. Dean and Son, Ltd., will issue:—"Guide to Queensland," by C. S. Rutlidge.

Mr. David Douglas (Edinburgh) announces:—"The Mineralogy of Scotland," by the late Prof. M. Forster Heddle, edited by J. G. Goodchild; "A Vertebrate Fauna of the Shetland Islands," by A. H. Evans and T. E. Buckley, illustrated; "Among British Birds in their Nesting Haunts," by O. A. J. Lee. Part 16, illustrated.

Messrs. Duckworth and Co.'s list contains:—"A Glossary of Botanic Terms," by Benjamin Daydon Jackson; "Agricultural Botany, Theoretical and Practical," by John Percival; "Country Matters in Short," by William Frederick Collier.

Mr. W. Engelmann (Leipzig) announces:—"Darstellung der 32 möglichen Krystallklassen," by Prof. Baumhauer, illustrated; "Die Lepra des Auges," by Dr. Borthen, illustrated; "Der Brückenbau," Erste Abteilung, edited by Prof. Th. Landsberg; "Neue Brückenbauten in Osterreich und Ungarn," by Prof. Foerster, illustrated; "Monographien afrikanischer Pflanzen-Familien und-Gattungen," edited by Prof. A. Engler; III. "Combretaceae-Combretum," by A. Engler and L. Diels; I. "Moraceae," by A. Engler; II. "Melastomaceae," by E. Gilg, illustrated; "Abriss der darstellenden Geometrie," by Prof. Gerland; "Conspectus Florae Graecae," by Dr. Halácsy, 1 Lieferung; "Strahlung und Temperatur der Sonne," by Prof. Scheiner.

Mr. S. T. Freemantle will publish a new library edition of the works of Gilbert White, including the "Natural History of Selborne," under the general editorship of Dr. Bowdler Sharpe, illustrated.

Messrs. R. Friedländer and Son (Berlin) promise:—"Das Tierreich," edited for the German Zoological Society by Fr. E. Schulze; "Lieferung 9: Trochilidæ," by E. Hartert: "Systematische Uebersicht der Ergebnisse seiner Reisen und schriftstellerischen Thätigkeit (1859–1899), by G. Finsch.

Messrs. Gauthier-Villars et Fils (Paris) promise:—"Leçons sur la Théorie des Formes ex la Géométrie analytique supérieure," by Andoyer; "La Télégraphie sans fil," by Broca; "Elémentes de la Théorie des nombres," by Cahen; "De Paris aux mines d'or d'australiè," by Chemin; "Recherches sur les réseaux," by Quesneville; "Traité pratique de Photogravure en relief et en creux," by Vidal; "Traité d'optique géométrique," by Wallon; "l'Objectif Photographique," by Lieut.-Colonel P. Moessard; "Œuvres Scientifiques," by Louis Raffy:—Mathématiques: Nouvelle théorie des fonctions exclusivement fondée sur l'idée de nombre. Physique: Physique mathématique (Distribution de l'Electricité, Hydrodynamique, Fragments divers), Thermodynamique générale (Equilibre et modifications de la matière). Chimie: Leçons de Chimie physique. "Essai des huiles essentielles," by H. Labbé; "La Métrophotographie," by Colonel A. Laussedat; "La Photocollographie," by G. Balagny; "Progrès de l'Electricité. Oscillations hertziennes. Rayons cathodiques et rayons X," by Prof. E. Bouty; "La Chronophotographie," by J. Marey; "Sur quelques Progrès récents accomplis avec l'aide de la Photographie dans l'étude du Ciel," by Dr. P. Puiseux; and a new edition of "Distribution de la vapeur. Epures de régulation. Courbes d'indicateur. Tracé des diagrammes," by A. Madamet.

Mr. L. Upcott Gill announces:—"British Dragonflies," by W. J. Lucas, illustrated:—"The Book of Gardening," a further supplement to Nicholson's Dictionary of Gardening.

The scientific announcements of Messrs. C. Griffin and Co., Ltd., are:—"Outlines of Bacteriology," by Dr. L. H. Thoinot and E. J. Masselin, translated and adapted for English use, with additions, by Dr. Wm. St. Clair Symmers, illustrated; "Dairy Chemistry for Dairy Managers, Chemists and Analysts," by H. D. Richmond; "Lubrication and Lubricants: a Treatise on the Theory and Practice of Lubrication and on the Nature, Properties and Testing of Lubricants," by Leonard Archbutt and R. Mountford Deeley; "The Metallurgy of Lead and Silver," by H. F. Collins, in 2 vols., each complete in itself, Part i.—Lead, Part ii.—Silver; "A Dictionary of Textile Fibres," by W. J. Hannan, illustrated; "Marine Meteorology," for officers of the merchant navy, by William Allingham, illustrated; "New Lands and their Prospective Advantages," by Dr. H. R. Mill; "Building Construction in Wood, Stone and Concrete," by James Lyon and J. Taylor; and a new edition of "Clinical Medicine: a Practical Handbook for Practitioners and Students," by Dr. Judson Bury, illustrated.

Mr. Heinemann's list includes:—"The Life of William Cotton Oswell," by his Son, W. E. Oswell, illustrated; "Innermost Asia: a Record of Travel and Sport in the Pamirs," by Ralph P. Cobbold, illustrated; "The World in 1900," a New Geographical Series, edited by H. J. Mackinder: (1) "Britain and the North Atlantic," by the Editor; (2) "Scandinavia and the Arctic Ocean," by Sir Clements R. Markham, K.C.B., F.R.S.; (3) "The Mediterranean and France," by Prof. E. Reclus; (4) "Central Europe," by Prof. J. Partsch; (5) "Africa," by Dr. J. Scott Keltie; (6) "The Near East," by D. G. Hogarth; (7) "The Russian Empire," by Prince Kropotkin; (8) "The Far East," by Archibald Little; (9) "India," by Colonel Sir Thomas Holdich; (10) "Australasia and Antarctica," by Dr. H. O. Forbes; (11) "North America," by Prof. I. C. Russell; (12) "South America," by Prof. J. C. Branner. "Telephotography: an Elementary Treatise on the Construction and Application of the Telephotographic Lens," by T. R. Dallmeyer, illustrated.

Among Messrs. Hutchinson's new books may be mentioned, "The Living Races of Mankind," by the Rev. H. N. Hutchinson, Dr. J. W. Gregory, and R. Lydekker, F.R.S.; "Disciples of Æsculapius," by the late Sir Benjamin Ward Richardson, F.R.S., with a biography of the writer by his daughter.

The Junior Army and Navy Stores give notice of "The Western Rajputana States, a Medico-Topographical and General Account of Marwar, Sirohi, Jaisalmir," by Lieut.-Colonel A. Adams.

Mr. John Lane calls attention to "The Natural History of Selborne," by Gilbert White, edited by Grant Allen, illustrated; "All About Dogs," by Charles Henry Lane, illustrated; "A Child's Primer of Natural History," by Oliver Herford, illustrated.

Messrs. Longmans and Co. announce new editions of "The Kinetic Theory of Gases," Elementary Treatise with Mathematical Appendices, by Prof. Oskar Emil Meyer, translated by R. E. Baynes, and "Coats' Manual of Pathology."

The list of Messrs. Sampson Low and Co., Ltd., includes:—"Experts on Guns and Shooting," by G. T. Teasdale Buckell, illustrated: "Twentieth Century Practice, an International Encylopædia of Modern Medical Science by leading Authorities of Europe and America," edited by Dr. Thomas L. Stedman.

In 20 vols., vol. xix., "Tuberculosis and Leprosy"; vol. xx., "Syphilis and General Index;" and new editions of "Instructions in Photography," by Captain W. de W. Abney, F.R.S.; "A Key to Engines and Engine Running," by J. Rose.

In the list of Messrs. Macmillan and Co., Ltd., we notice:—"Life and Letters of Thomas Henry Huxley, F.R.S.," by Leonard Huxley, with portraits and illustrations, 2 vols; "Life of James Hack Tuke," by the Right Hon. Sir Edward Fry, F.R.S., with portrait; "Notes on Sport and Travel," by the late Dr. George Kingsley, with introductory memoir by his daughter, Mary H. Kingsley, with portrait; "Malay Magic; being an Introduction to the Folklore and Popular Religions of the Malay Peninsula," by W. W. Skeat, illustrated; "A History of Modern Philosophy," by Dr. Harald Höffding, translated from the German by B. E. Meyer, 2 vols.; "The Social Philosophy of Rodbertus," by E. C. K. Gonner; "A Manual of Zoology," by the late Prof. T. J. Parker, F.R.S., and Prof. W. A. Haswell, F.R.S., illustrated; "Elementary Practical Zoology," by the late Prof. T. J. Parker, F.R.S., and Prof. W. Newton Parker, illustrated; "Elements of "Palæontology," by Prof. Karl A. von Zittel, translated and edited by Dr. Chas. R. Eastman, illustrated (this English edition is revised and enlarged by the author and editor in collaboration with numerous specialists); "Introduction to Physical Chemistry," by Prof. James Walker; "Dictionary of Political Economy," edited by R. H. Inglis Palgrave, F.R.S., vol. iii. (completing the work); "Micro organisms and Fermentation," by Alfred Jorgensen, translated by Dr. Alex. K. Miller and E. A. Lennholm, illustrated; "A System of Medicine," by many writers, edited by Prof. Thomas Clifford Allbutt, F.R.S., vol. viii. (concluding the work); "An Introduction to the Study of Mental Affections," by Dr. John Macpherson; "Introduction to the Outlines of the Principles of Differential Diagnosis, with Clinical Memoranda," by Dr. Fred. J. Smith; "A Manual of Medicine," edited by Dr. W. H. Allchin, in five vols.; "A Manual of Surgery," by Chas. Stonham, in three vols.; "Experimental Physiography for Section I. Physiography of the Science and Art Department," by Prof. R. A. Gregory and A. T. Simmons; "Building Construction for Beginners," by J. W. Riley; "Chemistry for Organised Schools of Science," by S. Parrish; "A Treatise on Elementary Dynamics, dealing chiefly with Motion in Two Dimensions," by H. A. Roberts; "Dictionary of Philosophy," edited by Prof. J. Mark Baldwin; "Methods of Knowledge," by Walter Smith; "First Experiments in Psychology," by Prof. Titchener; "The Hygiene of the School and of Instruction," by Edward R. Shaw; "Method in Education," by Walter L. Hervey; "The Study and Teaching of Geography," by Jacques W. Redway; "The Study and Teaching of Mathematics," by Principal David Eugene Smith; "Elementary Chemistry," by A. L. Arey; "An Encyclopedia of American Horticulture," by L. H. Bailey, in 3 vols.; "Practical Garden Book," by L. H. Bailey; "Irrigation," by Prof. F. H. King; "Thermodynamics," by E. Buckingham; "The Teaching Botanist," by Prof. William F. Ganong; "Elementary Electricity and Magnetism," by D. C. Jackson and J. P. Jackson; "The Myxomycetes, a Handbook of North American Slime Moulds," by Prof. Macbride; "Imperative Surgery, for the General Practitioner, the Specialist, and the Recent Graduate," by Dr. Howard Lilienthal; and a new edition of "An Atlas of Practical Elementary Biology," by Prof. G. B. Howes, F.R.S.

Messrs. Methuen and Co. give notice of:—"The Scientific Study of Scenery," by J. E. Marr, F.R.S.; "A Handbook of Nursing," by M. N. Oxford; "Practical Physics," by Prof. H. Stroud; "General Elementary Science," by Dr. J. T. Dunn and V. A. Mundella, illustrated; "The Metric System," by Leon Delbos; "The Highest Andes," by E. A. Fitzgerald, illustrated.

Mr. Murray will issue in his Progressive Science Series:—"On Whales," by F. E. Beddard, F.R.S., and "Heredity," by Prof. J. A. Thomson. He also announces:—"The Yang-Tse Valley and Beyond," by Mrs. Bishop, illustrated; "A Glimpse at Guatemala, and some Notes on the Ancient Monuments of Central America," by Annie Cary Maudslay and Alfred Percival Maudslay, illustrated; "Preparatory Geography for Irish Schools," by John Cooke, coloured and relief maps: "The Making of a Frontier, Five Years' Experiences and Adventures in Gilgit, Hunza Nagar, Chitral, and the Eastern Hindu-Kush," by Colonel Algernon Durand, illustrated; and a new edition of "The Natural History of Religion, based on the Gifford Lectures delivered in Aberdeen in 1889-90 and in 1890-91," by Prof. E. B. Tylor, F.R.S., illustrated.

Messrs. George Newnes, Ltd., announce:—"The Story of some Wandering Atoms, especially those of Carbon," by M. M. Pattison Muir; "The Story of Life's Mechanism," by H. W. Conn; "The Story of Thought and Feeling," by F. Rylands; "The Story of the Alphabet, with a brief account of some Ancient Records," by Edward Clodd, illustrated.

Mr. David Nutt's list contains:—"Problems of the Mycenæan Age," by H. R. Hall; "Egyptian Chronology," by F. G. Fleay.

Messrs. G. P. Putnam's Sons announce:—"Nature Studies in Berkshire," by the Rev. S. Coleman Adams, illustrated; "Birds that Hunt and are Hunted," by Neltje Blanchan, illustrated.

Messrs. Sands and Co. announce:—"Picturesque Kashmir," by Dr. A. Reve, with a chapter entitled "The Shaping of Kashmir," being a description of the geological formation and aspects of the country, illustrated; "Types of British Animals," by F. G. Aflalo, illustrated; "The Animals of Africa," by H. A. Bryden, illustrated; "Types of British Plants," by C. S. Colman, illustrated.

Messrs. Walter Scott, Ltd., will add to the Contemporary Science Series "The Races of Man: a sketch of Ethnography and Anthropology," by Dr. J. Deniker; and "The Psychology of Religion," by Prof. Starbuck, each illustrated.

Messrs. Smith, Elder and Co. promise:—"Health Abroad, a Medical Handbook for Travellers," edited by Dr. Edmund Hobhouse; Orthopædic Surgery," by C. B. Keetley, illustrated; "Lectures on the Practice of Medicine," by Dr. W. B. Cheadle, illustrated.

The science list of Messrs. Swan Sonnenschein and Co., Ltd., is as follows:—"The Victoria Nyanza: the Land, the Races and their Customs with specimens of some of their Dialects," by Lieut. P. Kollmann, illustrated; "The Antarctic," by Dr. K. Fricker, illustrated; "Aristotle's Psychology, including the Parva Naturalia," translated and edited with commentary and introduction by Prof. William A. Hammond; "A History of Contemporary Philosophy," by Prof. Max Heinze, translated by Prof. William Hammond; "Ethics," by Prof. W. Wundt, vol. iii.: "The Principles of Morality and the Sphere of their Validity," translated by Prof. E. B. Titchener; "Physiological Psychology," by Prof. W. Wundt, translated by Prof. E. B. Titchener, 2 vols. illustrated; "The Scientific Basis of Morality," by Dr. G. Gore, F.R.S.; "Text-book of Palæontology for Zoological Students," by Theodore T. Groom, illustrated; "Text-book of Embryology: Invertebrates," by Profs. E. Korschelt and K. Heider, vol. iii., translated from the German by Mrs. H. M. Bernard, and edited (with additions) by Martin J. Woodward, illustrated; "Mammalia," by the Rev. H. A. Macpherson; "Birds' Eggs and Nests," by W. C. J. Ruskin Butterfield; and new editions of "Handbook of Practical Botany for the Botanical Laboratory and private Students," by Prof. E. Strasburger, edited by Prof. W. Hillhouse, illustrated; "An Introduction to Zoology," by B. Lindsay, illustrated; "The Dog: its Management and Diseases," by Prof. Woodroffe Hill, illustrated; and "Introduction to the Study of Physiological Psychology," by Prof. Th. Ziehen, translated and edited by Dr. O. Beyer and C. C. Vanliew, with diagrams.

The list of the S.P.C.K. contains a new edition of "The Bible Atlas of Maps and Plans to illustrate the Geography of the Old and New Testaments, and the Apocrypha," with explanatory notes by the late Rev. Samuel Clarke, and a complete index of the geographical names in the English Bible, by Sir George Grove.

Mr Edward Stanford will issue:—"Europe, Vol. i., the Countries of the Mainland (excluding the North-West)," by George G. Chisholm, illustrated; "The Evolution of Geography, a Sketch of the Rise and Progress of Geographical Knowledge," by John Keane, illustrated.

Mr. T. Fisher Unwin calls attention to:—"Hermann Von Helmholtz," by Prof. J. G. McKendrick, F.R.S.; "Experiments on Animals," by Dr. S. Paget; "In Dwarf-Land and Cannibal Country," by A. B. Lloyd, illustrated; "From the Alps to the Andes," by M. Zurbriggen, illustrated.

Messrs. Frederick Warne and Co. promise:—"The Flowering Plants, Grasses, Sedges and Ferns of Great Britain," by Anne Pratt, edited and revised by Edward Step; "The Romance of Wild Flowers," by Edward Step, illustrated.

Messrs. Whittaker and Co.'s announcements are:—"Central Station Electricity," by A. Gay and C. H. Yeaman; "Arc

Lamps," by H. Smithson and E. R. Sharp: "English and American Lathes," by Joseph Horner; "Inspection of Railway Materials," by G. R. Bodmer; "The Modern Safety Bicycle," by H. A. Garratt; "Volumetric Chemical Analysis," by J. B. Coppock; "Elementary Practical Chemistry," by A. J. Cooper; new and revised editions of "The Atlantic Ferry," by A. J. Maginnis; "British Locomotives," by C. J. Bowen-Cooke; "Electric Light Cables," by Stuart A. Russell.

## *THE BRITISH ASSOCIATION.*

### SECTION K.

#### BOTANY.

OPENING ADDRESS BY SIR GEORGE KING, K.C.I.E., LL.D., F.R.S., PRESIDENT OF THE SECTION.

II.[1]

THE second period of our history begins with the arrival in India in 1848 of Sir (then Dr.) Joseph Hooker. This distinguished botanist came out in the suite of Lord Dalhousie, who had been appointed Governor-General of India. The province to the exploration of which Sir Joseph directed his chief attention was that of Sikkim in the Eastern Himalaya, the higher and inner ranges of which had never previously been visited by a botanist, for Griffith's explorations had been confined to the lower and outer spurs. The results of Sir Joseph's labours in Sikkim were enormous. Towards the end of his exploration of Sikkim he was joined by Dr. Thomas Thomson, and the two friends subsequently explored the Khasia Hills (one of the richest collecting grounds in the world), and also to some extent the districts of Sylhet, Cachar and Chittagong. Dr. Thomson subsequently amalgamated the collections made by himself in the Western Himalaya with those made in Sikkim by Sir Joseph individually, and by them both conjointly in Eastern India; and a distribution of the duplicates after the fashion of the Wallichian issue, and second only to it in importance, was subsequently made from Kew. The number of species thus issued amounted to from 6000 to 7000, and the individuals were much more numerous than those of the Wallichian collection. The immediate literary results of Sir Joseph Hooker's visit to Sikkim were (1) his superbly illustrated monograph of the new and magnificent species of *Rhododendron* which he had discovered; (2) a similar splendid volume illustrated by plates founded on drawings of certain other prominent plants of the Eastern Himalaya which had been made for Mr. Cathcart, a member of the Civil Service of India, and (3) his classic "Himalayan Journals"—a book which remains until this day the richest repertory of information concerning the botany, geography and anthropology of the Eastern Himalaya. A remoter result was the appearance in 1855 of the first volume of a "Flora Indica," projected by himself and his friend Dr. Thomson. The first half of this volume is occupied by a masterly introductory essay on Indian botany, of which it is hardly possible to overrate the importance. This remarkable essay contains by far the most important contribution to the physico-geographical botany of India that has ever been made, and it abounds in sagacious observations on the limitation of species and on hybridisation, besides containing much information on the history of Indian botanical collections and collectors. The taxonomic part of the book was cast in a large mould, and the descriptions were written in Latin. Unfortunately, the condition of Dr. Thomson's health and the pressure of Sir Joseph's official duties at Kew made it impossible that the book should be continued on the magnificent scale on which it had been conceived. After a period of about twelve years Sir Joseph, however, returned to the task of preparing, with the aid of other botanists, a Flora of the Indian Empire, conceived on a smaller scale and written in the English language. His proposals for this work were accepted and officially sanctioned by the Duke of Argyll while he was Secretary of State for India. The first part of this great work was published in 1872 and the last in 1897. In the execution of this great undertaking Sir Joseph had the assistance of Mr. C. B. Clarke, who elaborated various natural orders; of Mr. J. G. Baker, who worked out *Leguminosae* and *Scitamineae*, and of Sir W. Thiselton-Dyer, Messrs. A. W. Bennett, Anderson, Edgeworth, Hiern, Lawson, Maxwell Masters, Stapf and Gamble. The greater proportion, however, of the book is Sir Joseph's own work, and a noble monument it forms of his devotion and genius.

Since the date of Sir Joseph Hooker's visit to India, by far the most important botanical work done in India has been that of Mr. C. B. Clarke. Rather than attempt to give any appreciation of my own of Mr. Clarke's labours (which would be more or less of an impertinence), I may be allowed to quote from the preface to the concluding volume of the "Flora of British India" Sir Joseph's Hooker's estimate of them. Referring to all the collections received at Kew since the preparation of the "Flora" was begun, Sir Joseph writes: "The first in importance amongst them are Mr. C. B. Clarke's, whether for their extent, the knowledge and judgment with which the specimens were selected, ticketed, and preserved, and for the valuable observations which accompany them." Mr. Clarke has published numerous papers on Indian botanical subjects in the journals of the Linnean and other societies. He has issued as independent books monographs of Indian *Compositae* and *Cyrtandraceae*, the former in octavo, the latter in folio, and illustrated by many plates; and he is now engaged on his *opus maximum*, viz. a monograph of the *Cyperaceae*, not only of India, but of the whole world; and to the completion and publication of this every systematic botanist is looking forward with eager anxiety.

During this second half of the century, Dr. Thomas Anderson, who was for ten years superintendent of the Calcutta Garden, collected much; and he had just entered on what promised to be a brilliant career of botanical authorship when his life was cut short by disease of the liver, contracted during his labours to establish the cultivation in British India of the quinine-yielding species of cinchona. Dr. Anderson was also the earliest conservator of forests in Bengal. Sulpiz Kurz, for many years curator of the Calcutta Herbarium, also collected largely in Burma, and besides many excellent papers which he contributed to the *Journal* of the Asiatic Society of Bengal, he prepared for Government an excellent manual entitled the "Forest Flora of Burma." This was published in two volumes in 1877. Other collectors in Burma were Colonel Eyre (in Pegu), Mr. Burness (at Ava), and the Rev. Mr. Parish, to whom horticulturists are indebted for the introduction to Europe of the beautiful orchids of this rich province. And in this connection must be mentioned Mr. E. H. Man, C.I.E., who, although not himself a botanist, has given for many years past the greatest possible help in the botanical exploration of the Andaman and Nicobar groups of islands, our first knowledge of which was, by the way, derived from the collections made by the naturalists of the Austrian and Danish exploring expeditions. A large book on Burma, which contains a good deal of botany, was published by an American missionary named Mason, who resided for the greater part of his working life in that country. General Sir Henry Collett, who commanded a brigade during the last Burmese war, also made most interesting collections in that country, the novelties of which were described by himself in collaboration with Mr. W. Botting Hemsley, of the Kew Herbarium, in the Linnean Society's *Journal* some years ago. Sir Henry Collett also collected much in the Khasia and Naga hills, and in the portion of the North-western Himalaya of which Simla is the capital, and on these latter collections, together with the materials in Kew Herbarium, Sir Henry is now elaborating a local flora of Simla. The preparation of a local flora for an Indian district is an entirely new departure, and the publication of Sir Henry's book, which is to be well illustrated, is looked forward to with much interest. At rather an earlier period, Dr. Aitchieson was a diligent collector of the plants of the Punjab and of the North-western Frontier. Some results of his work are to be found in his "List of Punjab Plants," which was published in 1867, and in various papers which he contributed (some of them in conjunction with Mr. Hemsley) to the Linnean Society and to the Botanical Society of Edinburgh. In Dr. G. Henderson's book on Yarkand there are also descriptions of some plants of the extreme North western Himalaya and of Western Tibet. Mr. (now Sir George) Birdwood also made some contributions to the botany of the Bombay Presidency.

Five officers of the Indian Forest Department, viz. Dr. Lindsay Stewart, Colonel Beddome, Sir D. Brandis, and Messrs. Talbot and Gamble, have within the past thirty years made important contributions to the systematic botany of India. Dr.

[1] Continued from p. 584.

Stewart collected largely, and published in 1869 his "Punjab Plants," a book which gives a very imperfect impression of his acquirements as a botanist. Sir Dietrich Brandis issued in 1874 his admirably accurate "Forest Flora of the North-west Provinces of India," illustrated by seventy excellent plates. Between the years 1869 and 1873, Colonel Beddome issued his "Flora Sylvatica of the Madras Presidency," illustrated by numerous plates. He also published, between 1869 and 1874, a volume of descriptions and figures of new Indian plants, under the title "Icones Plantarum Indiæ Orientalis." Colonel Beddome is the only Indian botanist of note, except Griffith, Mr. C. B. Clarke and Mr. C. W. Hope, who has written much on Indian ferns. His two works, the "Ferns of Southern India" and the "Ferns of British India," published the former in 1863 and the latter between 1865 and 1870, practically give a systematic account, together with excellent figures, of the whole fern flora of India. Of these excellent books a condensation in a popular and abridged form has also been issued. The fourth forest officer who has published contributions to systematic botany is Mr. W. A. Talbot, whose "List of the Trees, Shrubs and Woody Climbers of the Bombay Presidency" gives evidence of much careful research. And the fifth is Mr. J. S. Gamble, who, besides amassing at his own expense probably the largest private collection of plants ever owned in India, has published a systematic account of the Indian *Bambuseae*, a tribe of grasses which, from the peculiarity of many of the species in the matter of flowering, had so long been the bane of the Indian agrostologist. Mr. Gamble, in his monograph, gives a description and a life-sized figure of every one of the Indian species. Of this monograph (which forms a volume of the "Annals of the Botanic Garden, Calcutta") Sir Joseph Hooker writes (at p. 375. vol. vii. of his "Flora of British India"): "It is indispensable to the student of the tribe by reason of its descriptions and admirable plates and analyses." Mr. Gamble has also published a Manual of Indian Timbers. A forest officer who was ever ready to help in botanical work, but who never himself published, was Mr. Gustav Mann, for many years Conservator of Forests in Assam, but now lost to India by his premature retirement. Other forest officers, who have done, and are still doing, good botanical work in their various spheres, are Messrs. Lace, Heinig, Haines, McDonell, Ellis, Oliver, and Upendra Nath Kanjilal. Mr. Bourdillon, conservator of forests in the Travancore State, is also an enthusiastic botanist and collector.

In the Madras Presidency botanical work has been carried on during this second half of the century by Noton, Perrottet, Metz, Hohenacher, Schmidt (on the Nilgiris), Bidie and Lawson. By the efforts of the latter two, a second public herbarium was established in Madras (the first having been broken up many years ago), and in this second Madras herbarium are to be found many of the collections of Wight, besides those of the other Madras botanists just named.

In the Bombay Presidency, the only public herbarium is at Poona. This is of recent origin, and owes its existence to the devotion of four men, viz. Dr. Theodore Cooke (late principal of the College of Science at Poona), Mr. Marshall Woodrow (until recently superintendent of the garden at Guneshkind and lecturer in botany in the Poona College), the late Mr. Ranade (a native gentleman), and Dr. Lisboa (a medical practitioner in the Deccan)—all four enthusiastic botanists. The amount of Government support given to the herbarium at Poona has hitherto been very inadequate. It is to be hoped that greater liberality may be extended to it now that a stranger to the Bombay Presidency has just been appointed to its charge in the person of Mr. George Gammie, hitherto employed in the cinchona department of Bengal.

Reference has already been made to the botanic gardens at Seharunpore and Calcutta. But to complete this sketch, and especially in order to give a clear idea of the apparatus at present existing in India for carrying on the study and practice of systematic botany, it is necessary again to refer to them. On the retirement of Dr. Jameson in 1872, Mr. J. F. Duthie was selected by the Secretary of State for India as superintendent of the Seharunpore garden. Mr. Duthie is still at Seharunpore. During his tenure of office he has added to the herbarium previously existing there (which consisted chiefly of the collections of Royle, Falconer and Jameson) a magnificent collection of his own. Mr. Duthie has published a valuable book on the "Field and Garden Crops of the North-western Provinces," and another on the grasses of the same area. He is now engaged on the preparation of local floras of the North-west Provinces and of the Punjab.

The Calcutta Garden at the date of Sir J. D. Hooker's arrival in India in 1848 was under the charge of Dr. Falconer, who, in 1855, was succeeded by Dr. J. Thomson, and he in turn by Dr. T. Anderson in 1861. Mr. C. B. Clarke acted as superintendent during the interregnum between Dr. Anderson's lamented death in 1870 and my own appointment in 1871. The garden and herbarium at Calcutta have been most liberally supported by the Government of Bengal. By funds thus supplied the garden has been remodelled and improved; the herbarium has been housed in an excellent fire-proof building (erected in 1883), and the collections of which it consists have been greatly increased. The chief items of these later acquisitions have been the large contributions of Mr. C. B. Clarke; of Dr. D. Prain, for many years curator of the herbarium, and now superintendent of the garden and of the cinchona plantation and factory; of Mr. G. A. Gammie, formerly one of the staff of the cinchona plantation, and now lecturer on botany in the College of Science at Poona; of Mr. R. Pantling, deputy-superintendent of the cinchona plantation, who, in addition to dried specimens of the orchids of Sikkim, contributed nearly five hundred drawings, most of which have been lithographed as the illustrations to a book published in the "Annals" of the garden, as the "Orchid Flora of Sikkim"; of Mr. Kunstler, a collector in the Malay Peninsula; and last, but by no means least, of a trained band of aborigines of Sikkim named Lepchas who possess keener powers of observation of natural objects, more patience, sweeter tempers, and, I am bound in fairness to add, dirtier clothes than any race I have ever met—black, yellow, or white! In addition to their liberal grants to the garden and herbarium, the Bengal Government, twelve years ago, sanctioned the publication, at their expense, as occasion might offer, of monographs of important families or genera of Indian plants. These monographs are printed in quarto, and they are, with one exception, profusely illustrated by plates drawn and lithographed by Bengali draughtsmen. The series is known as "The Annals of the Royal Botanic Garden, Calcutta," and it has now reached its eighth volume, the ninth being in active preparation. These "Annals" have been contributed to by Dr. Prain (my successor at the Calcutta Garden), by Dr. D. Douglas Cunningham, Mr. J. S. Gamble, Mr. R. Pantling, and myself.

About ten years ago, it occurred to the Supreme Government of India that it might be to the interest of science if the four botanical establishments at Calcutta, Seharunpore, Madras, and Poona were to be formed into a kind of hierarchy under the designation of the Botanical Survey of India, without removing either the officers or the four institutions to which they were attached from the financial or general control of the local administrations within which they are respectively situated, the Supreme Government making a small contribution of money for the purpose of exploring little-known districts and making itself responsible for the cost of a publication called "The Records of the Botanical Survey." The four institutions just mentioned continue, therefore, to be paid for and controlled by the Governments of Bengal, the North-west Provinces, Madras and Bombay, but their superintendents are placed on the cadre of the Botanical Survey. The published Records of this Survey now extend to twelve numbers, each of which is devoted to an account of the botany of some part of the enormous and continually expanding area to be explored.

Such, then, is the machinery by which systematic, as distinguished from economic and physiological, botany is carried on within the Indian Empire. But the work done in India itself by no means represents all the work that is being carried on in connection with the elucidation of the flora of the Empire of India. On the contrary, the bulk of the work of elaborating the materials sent from India in the shape of dried specimens has always been, and must always be, done in a large herbarium; and until lately no herbarium in Asia has been sufficiently extensive. The last word on every difficult taxonomic question must still lie in Europe. A very large number of the herbarium specimens collected in India have found their way to the various centres of botanical activity in Europe, and have been described by botanists of many nationalities. The lion's share of these specimens has naturally come to the two great national herbaria in the British Museum and at Kew, but especially to the latter. It was in the Kew Herbarium that Sir Joseph Hooker and his collaborateurs prepared the flora of

British India. And it is in the Kew Herbarium that are to be found the types of an overwhelming proportion of the new species described for the first time in that monumental work. The Kew Herbarium is therefore to the Indian botanist the most important that exists. I must apologise for diverging for a moment to remind you what a type specimen is. It is the very one on which an author has founded any species to which he has given a name. And in order to determine absolutely what is the specific form to which the author meant his name to apply, it is often necessary to examine his type. This necessity increases in urgency with the extension of our knowledge of the flora of the world.

The preservation in good condition of a type specimen is therefore, from the point of view of a systematic botanist, as important as is the preservation to the British merchant to the standard pound weight and the standard yard measure on which the operations of British commerce depend. "Types" also stand to the systematic botanist much in the same relation as the national records do to the national historian. The latter are guarded in the Record Office, I understand, with all the skill which the makers of fire-proof, damp-proof and burglar-proof depositories can suggest. If, however, the type of a species happens to be deposited at Kew, what are the probabilities of its preservation? Such a type at Kew is incorporated in what is admittted to be in every sense the largest and, for its size, the most accurately named, the most easily consulted, and therefore the most valuable herbarium in the world, the destruction of which would be a calamity commensurate in extent with that of the burning of the library at Alexandria. One might therefore reasonably expect that a people who rather resent being called a "nation of shopkeepers" would feel pride in providing for this priceless national collection a home which, although perhaps somewhat inferior to that provided for the national historical records, might at least be safe from fire. This expectation is not fulfilled. The infinitely valuable Kew Herbarium and library have no safer home than an old dwelling-house on Kew Green, to which a cheap additional wing has been built. The floor, galleries and open inner roof of this additional wing are constructed of pine coated with an inflammable varnish, and on the floor and galleries are arranged cabinets (also made of pine-wood) in which the specimens (which are mounted on paper) are lodged. The provision of a fireproof building, capable of expansion as the collections extend, is surely not beyond the means of an exchequer which last year netted over one hundred and six millions sterling of revenue. On behalf of the flora of India, I venture to express the hope that the provision of a proper home for its types may receive early and favourable consideration by the holders of the national purse-strings. But India is by no means the only portion of the Empire interested in this matter, for the types of the Australasian floras, those of a large part of the North American flora, and those of many species inhabiting countries outside British rule or influence, find their resting-place at Kew. The safe custody of the Kew Herbarium is, therefore, not merely a national, but a cosmopolitan responsibility.

In this Address I have hitherto made little reference to cryptogamic and economic botany. As regards cryptogamic botany there is little to relate. Except Griffith, no Indian botanist of the earlier of the two periods into which I have divided my sketch ever did any serious work amongst non-vascular cryptogams. During the second period two men have done gallant work under difficulties which no one who has not lived in a tropical country can thoroughly appreciate. I refer to Drs. Arthur Barclay and D. D. Cunningham. The former made some progress in the study of uredinous fungi, which was cut short by his untimely death; while the latter, in addition to his bacterial and other researches connected with the causation of human disease, conducted protracted investigations into some diseases of plants of fungal or algal origin. Some of the results of Dr. Cunningham's labours were published in the *Transactions* of the Linnean Society, and in a series entitled the "Scientific Memoirs, by Medical Officers of the Indian Army." To the "Annals of the Botanic Garden, Calcutta," Dr. Cunningham also contributed elaborate memoirs on the phenomena of nyctitropism, and on the mode of fertilisation in an Indian species of Ficus (*F. Roxburghii*). There is no doubt that, in the past, cryptogamic botany has not been studied in India as it ought to have been and might have been. This discredit will, I hope, be soon removed; and I trust that, by the time the twentieth century opens, a cryptogamist may have been appointed to the staff of the Calcutta Botanic Garden. The collecting of cryptogams was not, however, altogether neglected in India in times past. For, from materials sent to England, Mitten was able to elaborate a moss flora of India, while Berkeley and Browne were enabled to prepare their account of the fungi of Ceylon. George Wallich, in whom the botanical genius of his father burnt with a clear though flickering flame, did some excellent work amongst Desmids, and was among the earliest of deep-sea dredgers.

Economic botany has, on the other hand, by no means been neglected. It was chiefly on economic grounds that the establishment of a botanic garden at Calcutta was pressed upon the Court of Directors of the East India Company. And almost every one of the workers whose labours I have alluded to has incidentally devoted some attention to the economic aspect of botany. Roxburgh's "Flora Indica" contains all that was known up to his day of the uses of the plants described in it. Much of Wight's time was spent in improving the races of cotton grown in India. The botanists of the Seharunpore garden during the middle of the century were especially prominent in this branch of botanical activity. Royle wrote largely on cotton and on other fibres, on drugs, and on various vegetable products used, or likely to be of use, in the arts. These botanists introduced into the Himalayas more than fifty years ago the best European fruits. From gardens which owe their origin to Royle, Falconer and Jameson, excellent apples grown in Gharwal and Kamaon are to-day purchasable in Calcutta. Peaches, nectarines, grapes, strawberries, of European origin, are plentiful and cheap all over the North-west Himalaya, and are obtainable also in the submontane districts. Potatoes, and all the best European vegetables, were introduced long ago; and at Seharunpore there is still kept up a large vegetable garden from which seeds of most European vegetables are issued for cultivation during the cold season in the gardens of the various regiments of the Queen's troops quartered in Upper India. More or less attention has been given in the past by Government botanists in India generally to the improvement of the cultivation of flax, hemp, rheea, tobacco, henbane, dandelion, vanilla, sarsaparilla, coffee (Arabian and Liberian), cocoa, ipecacuanha, aloes, jalap, india-rubber, Japanese paper-mulberry, cardamoms, tapioca, coca, tea and cinchona. Only to three economic enterprises, however, have I time to allude in any detail. These are (1) the cultivation of tea, (2) the introduction of cinchona, and (3) the formation of the Forest Department. But before proceeding to the consideration of these I wish to give a short account of the inauguration of the office of Reporter on Economic Products. Up to the year 1883 there had been no special Government department in India for dealing with questions connected with the natural products of the Empire. Whatever had been done prior to that date (and the amount was by no means unimportant) had been the result of isolated and uncoordinated effort. In 1883 the Government of India founded a department for dealing with the economic products of the Indian Empire, and under the title of Reporter on these products they were fortunate enough to secure Dr. George Watt, a member of the Bengal Educational Service. Dr. Watt is an accomplished and able botanist. He has collected Indian plants largely, and has made numerous notes both in the field and in the bazaar. The great work which, on the initiative of Sir Edward Buck, Secretary to the Department of Revenue and Agriculture, and of Sir W. Thiselton-Dyer, of Kew, Dr. Watt began and carried to a successful termination was the compilation of his "Dictionary of Economic Products," in which valuable book is collected all that is known of almost every Indian product, whether vegetable, animal or mineral. The study of economic botany is now pursued in India as part of a highly specialised system of inquiry and experiment. Dr. Watt has a competent staff under him in Calcutta, one of whom is Mr. D. Hooper, well known for his original researches into the properties of various Indian drugs. Dr. Watt has arranged in Calcutta a magnificent museum of economic products, and there is no doubt the economic resources of the Empire are now being studied with as much energy as intelligence.

Tea cultivation is one of the enterprises in the introduction and development of which botanists took a very leading part. The advisability of introducing the industry was first pressed on the attention of the East India Company by Dr. Govan (of Seharunpore), and in this he was seconded by Sir Joseph Banks as President of the Royal Society. Royle in 1827, and Falconer

slightly later, again urged it as regards the North-west Himalaya. In 1826 David Scott demonstrated to rather unwilling eyes in Calcutta the fact that real tea grows wild in Assam. In 1835 Wallich, Griffith and McClelland were deputed by Government to visit Assam, to report on the indigenous tea. In the year 1838 the first consignment of Indian-grown tea was offered for sale in London. The consignment consisted of twelve chests containing 20 lbs. each. This first sample of 240 lbs. was favourably reported upon. Last year the exports of tea from India to all countries reached 157 millions of pounds, besides 120 millions of pounds exported from Ceylon!

The introduction of cinchona into India originated purely with the Government botanists. As everybody knows, quinine, and to a less extent the other alkaloids present in cinchona bark, are practically the only remedies for the commonest, and in some of its forms one of the most fatal, of all Indian diseases, viz. *malarious fever*. The sources of supply of the cinchona barks in their native countries in South America were known to be gradually failing, and the price of quinine had for long been increasing. The advisability of growing cinchona in the mountains of British India was therefore pressed upon Government by Dr. Royle in 1835, and he repeated his suggestions in 1847, 1853 and 1856. Dr. Falconer, in his capacity of superintendent of the Botanic Garden, Calcutta, made a similar suggestion in 1852; and his successors at Calcutta, Dr. T. Thomson and Dr. T. Anderson, in turn advocated the proposal. In 1858 Government at last took action, and, as the result of the labours of Sir Clements Markham and Sir W. J. Hooker, of Kew, the medicinal cinchonas were finally, in the period between 1861 and 1865, successfully introduced into British India—on the Nilgiris under Mr. McIvor, and on the Sikkim-Himalaya under Dr. T. Anderson. Various experiments on the best mode of utilising the alkaloids contained in red cinchona bark resulted in the production in 1870 by Mr. Broughton, quinologist on the Nilgiri plantation, of an amorphous preparation containing all the alkaloids of that bark. This preparation was named *Amorphous Quinine*. Somewhat later (1875) a similar preparation, under the name of *Cinchona Febrifuge*, was produced at the Sikkim plantation by Mr. C. H. Wood, the quinologist there; and of these drugs about fifty-one tons have been distributed from the Sikkim plantation up to the end of last year. The preparation of pure quinine from the yellow cinchona barks, so successfully grown in the Sikkim plantation, long remained a serious problem. The manufacture of quinine had hitherto been practically a trade secret. And when the Indian Government had succeeded in providing the raw material from which a cheap quinine might be made for distribution amongst its fever-stricken subjects, the knowledge of the means of extracting this quinine was wanting. Philanthropic platitudes were freely bandied about as to the immensity of the boon which cheap quinine would be to a fever-stricken population numbering so many millions. But there was a singular absence of any practical help in the shape of proposals, or even hints, as to how quinine was to be extracted from the rapidly increasing stock of crown and yellow bark. The officers in charge of the cinchona plantations in India had therefore to do their best to solve the problem for themselves. And it was ultimately solved by Mr. C. H. Wood, at one time Government quinologist in Sikkim, who suggested, and Mr. J. A. Gammie, deputy-superintendent of the plantation there, who carried into practice, a method of extraction by the use, as solvents of the cinchona alkaloids, of a mixture of fusel-oil and petroleum. The details of this process were published in the *Calcutta Official Gazette*, for the benefit of all whom it might concern. Very soon after the introduction of this method of manufacture, the Government factories in Sikkim and the Nilgiris were able to supply the whole of the Government hospitals and dispensaries in India with all the quinine required in them (some 5000 or 6000 pounds annually), besides providing an almost equal quantity for the supply of Government officers for charitable purposes. The latest development of the quinine enterprise in India has been the organisation of a scheme for the sale at all the post-offices in the province of Bengal, and in some of those of Madras, of packets each containing five grains of pure quinine, that being a sufficient dose for an ordinary case of fever in a native of India. These packets (of which some are on the table for distribution) are sold at one pice each, the pice being a coin which is equal, at the current rate of exchange, to one farthing sterling!

In conclusion, I wish to make a few remarks on the third great economic enterprise connected with botany in India, viz. the Forest Department. The necessity for taking some steps to preserve a continuity of supply of timber, bamboos and other products from the jungles which had for generations been exploited in the most reckless fashion, was first recognised by the Government of Bombay, who in 1807 appointed commissioners to fix the boundaries of and to guard the forests in that Presidency. This scheme was abandoned in 1822, but was resumed in a modified form during 1839–40. Seven years later a regular forest service was established in Bombay, and Dr. Gibson was its first head. Dr. Gibson in turn was succeeded by Mr. Dalzell—and both were botanists. In the Madras Presidency the first man to recognise the necessity of perpetuating the supply of teak for ship-building was Mr. Connolly, collector of Malabar, who in 1843 established a teak plantation at Nelumbur, which has been carried on, and annually added to, down to the present time. In 1847 Dr. Cleghorn (a botanist) was appointed to report on the conservation of the forests of Mysore (which contained the well-known sandal-wood), and the following year Lieutenant Michael (still with us as General Michael, a hale and hearty veteran) was appointed to organise and conserve the public forests in Coimbatore and Cochin. The crowning merit of General Michael's administration was the establishment, for the first time in India, of a system of protection against the fires which annually used to work such deadly havoc. In 1850 the British Association, at their Edinburgh meeting, appointed a committee to consider and report upon the probable effects, from an economic and physical point of view, of the destruction of tropical forests. This committee's report was submitted to the Association at the meeting at Ipswich in 1851. The weighty evidence collected in this report so impressed the Court of Directors of the East Indian Company that, within a few years, regular forest establishments were sanctioned for Madras and British Burma, the two main sources of the supply of teak.

In 1856 Mr. (now Sir Dietrich) Brandis was appointed to the care of the forests of the latter province. These forests had been the object of spasmodic efforts in conservancy for many years previously. In 1827 Dr. Wallich reported on the teak forests, and five years later a small conservancy establishment was organised, officered by natives. This, however, was kept up for only three or four years. In 1837 and 1838 Dr. Helfer reported on these forests, and an English conservator was appointed. In 1842 and 1847 codes of forest laws were drawn up, but do not appear to have been enforced to any extent. In 1853 Dr. McClelland was appointed superintendent, but he continued to hold the office for only a short time. A few years after Sir Dietrich Brandis's assumption of the charge of the Burmese forests, he was appointed Inspector-General of all the Government forests in British India; and it is to him that we owe for the most part the organisation of the Indian Forest Department as it now exists. That organisation includes two schools of forestry (in both of which botany is taught), one in connection with Coopers Hill and the other at Dehra Dun in Upper India. The latter has for many years been under the direction of a gentleman who is distinguished both as a forester and as a botanist. In the Coopers Hill School the higher grades of forest officers receive their training; at Dehra Dun those of the lower grades receive theirs. The officers of the department on the Imperial list, according to the latest official returns, now number 208, divided into the grades of conservator, deputy- and assistant-conservator, with a single inspector-general as chief. In addition to these, there are 566 provincial officers, ranking from rangers upwards to extra deputy-conservators.

Botanists took a leading part in moulding the department in its earlier years; for, as already stated, its pioneers—Gibson, Dalzell, Cleghorn, Anderson, Stewart and Brandis—were all botanists. And to most people, who give even casual attention to the matter, it appears fitting that the possession of a knowledge and liking for botany should form a strong characteristic of officers whose main duties are to be in the forest. And this belief did for some time exercise considerable influence in the selection of recruits for the department. But, except in the Dehra Dun School, it does not appear to guide the department any longer. For example, at the entrance examination to the Forest School at Coopers Hill, only three subjects are obligatory for a candidate, viz. mathematics, to which 3000 marks are allowed; German, to which 2000 are allowed; and English, for which 1000 are given. Botany is one of the nine optional

subjects, of which a candidate may take up two, and in each of which 2000 marks may be made.

Botany is taught at Coopers Hill, and (according to the Calendar of the College) it forms one of the "special auxiliary subjects" for the forest student. I do not wish to say a single word in depreciation of the botanical teaching at this college, which is probably excellent of its sort. I do not know what value, as part of their professional equipment, students are accustomed or encouraged to attach to the possession of the means of acquiring a knowledge of the trees and shrubs in the midst of which they are to pass their lives in India. But this I do know, that the ordinary forest officer educated in England now arrives in India without sufficient knowledge to enable him to recognise from their botanical characters the most well-marked Indian trees. To tell such an officer the name of the natural family to which a plant belongs conveys no information to him whatever, for he knows nothing of botanical affinities. Moreover, the forest officer after he has arrived in India is not encouraged to familiarise himself with the contents of the forests under his charge. This will be better appreciated by giving an example than by any number of remarks. Some three years ago, Mr. J. S. Gamble (a forest officer) published a monograph of the bamboos of British India. From bamboos, as you may possibly be aware, a very large amount of forest revenue is annually derived. The sales of bamboos for the year 1896 97 amounted to no less than 110 millions of stems. A great number of the species of bamboos have the curious habit of flowering gregariously at remote intervals of thirty or forty years, and the flowering is followed by death. The absence from the forests for years in succession of flowers of a number of the species, and the similarity of many of them in leaves, had hitherto made members of the group most difficult of identification. Mr. Gamble had devoted himself to their study for many years. He had carefully examined all the previously collected materials stored in the herbaria at Kew, the British Museum, Calcutta and elsewhere; and large special collections had been made for him by Mr. Gustav Mann and other officers of the Government. Moreover, he had General Munro's great paper in the Linnean *Transactions* as a basis. Mr. Gamble's work was undertaken with the full approval of Sir Joseph Hooker, who indeed accepted Mr. Gamble's account of the bamboos for his "Flora of British India." Mr. Gamble's monograph is illustrated by a life-sized drawing of each species, with analyses of the flowers on a larger scale. When completed, the book was published as one of the volumes of the "Annals of the Calcutta Botanic Garden." In consideration of the supposed great importance of the book to the forester, and in the belief that the copies would be eagerly taken by the Forest Department, an extra hundred copies were printed, and these hundred copies were put into stout canvas binding suitable for camp use. These copies, or as many of them as he cared to take, were offered to the head of the Forest Department in India at the reduced price of fifteen rupees per copy. The result was an official refusal to buy a single one, although the purchase of the whole hundred (which was not asked for) would have cost only fifteen hundred rupees—a sum which would have reduced the revenue of the year by about one twelve-thousandth part! An appeal against this ruling having been made to a still higher authority, a modified order was subsequently issued permitting such forest officers as desired to possess the book to buy copies and charge the cost in their office expenditure. I may state that the book was not a private venture. It was produced at the expense of the Government of Bengal.

It is not because I like to play the censor that I have made these remarks about the Forest Department. Having myself served in it from 1869 to 1871, I can speak from my own experience as to the value, from the utilitarian point of view, of a knowledge of the names, affinities and properties of the trees, shrubs and herbs which compose an Indian jungle, and of a knowledge of these as individual members of the vegetable kingdom rather than as masses of tissue to be studied through a microscope. The appointment which I held in India for twenty-six years after leaving the Forest Department gave me full opportunity of getting into touch with all who interest themselves in a knowledge of plants, and of discovering how few of these at the present day are forest officers. The majority of the latter, if they love their trees, are content to do so without knowing their names or relationships! There are, of course, splendid exceptions who know as well as love. The general decadence of the teaching of systematic botany in England during the past twenty years is, perhaps, to some extent the cause of the low estimation in which the science is held by the authorities of the Indian Forest Department. Twenty-five years ago systematic and morphological botany, no doubt, had too great prominence given to them in the teaching at universities and colleges of this country, and the other branches of botanical science were too much neglected, although I do not think they were despised. Now it appears to me that systematic botany is too much neglected. I hope it is not also despised! Few of the systematists who survive in England are now to be found attached to the universities. They are mostly clustered round the two great herbaria in London; and such of them as have to look to systematic botany for the means of livelihood are not in the receipt of salaries such as one might reasonably expect in one of the richest countries in the world!

## *CHEMISTRY AT THE BRITISH ASSOCIATION.*

DESPITE the fact that the Dover meeting was a comparatively small one, the chemists formed a thoroughly representative gathering, including amongst distinguished foreigners Prof. Lemoine, of Paris; Prof. Fittig, of Strassburg; and Prof. Ladenburg, of Breslau. The able address of the President, Dr. Horace T. Brown, on the assimilation of carbon by the higher plants, which embodied most valuable and original contributions to the knowledge of the complex changes which go on in the living cell, introduced a subject somewhat beyond the usual scope of the proceedings of the Section; and whilst the chemists present at Dover will always look back upon the address with a special appreciation, they will be equally mindful of the many interesting contributions on kindred subjects for which the personality of the President was in the main responsible. Prof. Hanriot, the President of the Chemical Section of the French Association, communicated a short account of the excretory products of plants, in which he discussed the mutations of nitrogen in the vegetable kingdom as based on his own observation of the occurrence of asparagine amongst the secretions of plant roots; when passed into the soil this product would in all probability become oxidised to nitrates, and thus become directly available for plant life. The experimental confirmation of this view is in course of study. The chemical processes involved in the saccharification of starch by malt-diastase were discussed by Dr. A. Fernbach, of the Institut Pasteur, and by Dr. G. H. Morris. The former detailed his observations on the influence of acids and of some salts on saccharification, which led him to the conclusion that the slightest trace of any free acid retards the action of diastase on gelatinised as well as on soluble starch, provided both the starch and diastase are free from salts on which the added acid may act; but if the solution contains salts, such as secondary phosphates, which are distinctly unfavourable to diastatic action, the addition of acid is favourable as long as there is no excess over the quantity necessary to transform these salts into the primary phosphates. The President regarded these results as opposed to his own observations on the subject, and considered further details of the experiments necessary to justify the conclusions. Dr. G. H. Morris, in a paper on the combined action of diastase and yeast on starch granules, showed that similarly to the symbiotic action of diastase and yeast on the so-called stable dextrin, ungelatinised intact starch granules, when submitted to the joint action of diastase and yeast, are fermented to a large extent, the maltose first formed being converted into alcohol. The addition of a small quantity of yeast to a cold water malt extract more than doubles the percentage of starch that is changed, and this increased action is not due to any greater activity of the diastase that might result from the removal of the soluble product formed (maltose) from the sphere of action. It appears necessary to have both the diastase and the yeast present together in a condition capable of exercising their respective functions for the increased action to occur. The action of acids on starch was also discussed by Dr. Morris, who showed that maltose is always obtained as a product of hydrolysis together with dextrin and dextrose; this is in opposition of H. Johnson's statement that the two latter compounds are the sole products of the action. But the most interesting contribution to this branch of chemistry was the joint discussion with Section K (botany) on symbiotic fermentation, on the occasion of the visit of the French Association. The discussion

was opened by Prof. Marshall Ward, who was followed by Sir Henry Roscoe, Prof. Armstrong, M. van Laar, Prof. Reynolds Green, Prof. Warington, M. Tanret, Prof. Francis Darwin and Dr. G. H. Morris. There is little doubt that the discussion has led to a more exact recognition of the division and relations of symbiotic changes, which should serve to develop the study of the subject. Prof. Marshall Ward, after considering the conditions under which symbiosis exists both in the vegetable and animal kingdoms, passed to the more special subject of symbiotic fermentations. Prof. Ward instanced the various grades of symbiotic association that may be recognised, suggesting a special nomenclature, and concluded his remarks with the consideration of the physiology of the subject. The many possibilities that may arise in the mutual life of symbiotic organisms—such as the provision of definite food material by one symbiont for the other, or the advantage derived from a protective influence, or, finally, the exertion of a stimulating action—were discussed, with the conclusion that there is some evidence to support the hypothesis that one symbiont may stimulate another by excreting a body which acts as an exciting drug to the associated organism. The chemical aspect of the subject was concisely treated by Prof. Armstrong, who pointed out that there is an absence of positive evidence to show that one member of a pair of symbiotic organisms does more than prepare the way for the other by effecting a change which the second is incapable of inducing. The possibility of chemical interaction playing a part in symbiotic changes and the hydrolytic function of enzymes were clearly brought out, and illustrations of allied changes of a purely chemical character instanced. Prof. Armstrong pointed out that no case has yet been observed in which a substance is attacked by a pair of organisms neither of which can attack it singly, and regarded it as probable that associated molecules undergo change under the influence of a single organism or agent which determines their association. Prof. van Laar, on the other hand, expressed the view that symbiosis was rather a case of parasitism. Dr. Calmette's contribution on industrial symbiotic fermentations was read, in his unavoidable absence, by Sir Henry Roscoe. In this paper an account was given of the methods for the conversion of starch into alcohol by the association of pure cultures of moulds with pure yeast cultures, and the industrial application of this symbiotic relation. Both in France and in Belgium thousands of tons of starch are now converted into alcohol by this method, and most favourable results have been obtained both as regards yield and quality. In inorganic chemistry Prof. Dewar's important experiments on the solidification of hydrogen stands foremost; an account of these researches has already appeared in NATURE. Colonel Waterhouse contributed a note on a remarkable result he has observed on the exposure of metallic silver to light; a visible image results on the exposed plate after prolonged exposure, but the effect may be recognised in a very much shorter space of time by the development of the latent image produced. An important discussion on the proposal of establishing an International Committee on Atomic Weights was initiated by Prof. F. W. Clarke in the form of a letter to Prof. Tilden, who himself contributed a critical *résumé* of both the theoretical and practical aspects of the question. In view of the proposed discussion of the subject at the Congress of Chemists to be held in Paris next year, Prof. Clarke's proposal for an International Committee aroused much interest; but the exact scope of its work appeared difficult to define in the minds of Sir Henry Roscoe, Prof. Fittig, Sir William Crookes and others who participated in the discussion. The desirability of encouraging all capable of undertaking the redetermination of atomic weights was fully recognised, but such work could not be ordered. This view, of course, referred to the theoretical part of the problem; Prof. Tilden's suggestion regarding the desirability of an understanding as to the numbers to be chosen for ordinary use was somewhat lost sight of by many of the speakers, especially his important addendum that the values arrived at in atomic weight determinations are obtained under conditions which cannot be observed in daily laboratory practice, and that the adoption, therefore, of numbers regarded as the most exact does not of necessity contribute to the exactness of ordinary analytical observations. Dr. Gladstone's report on the teaching of natural science in elementary schools was followed by an interesting discussion; Dr. Gladstone, in conjunction with Mr. Hibbert, also contributed a paper dealing with some peculiarities in the drying of colloids such as the hydrates of silica, tin, titanium, iron and alumina.

The papers, reports, and discussions dealing with organic chemistry were of more than usual importance. Prof. Hartley read the first report of his committee on the absorption spectra and chemical constitution of organic substances, which, in addition to the work of the committee, contains a valuable summary of that of other investigators. The committee on the action of light upon dyed colours issued their final report, which completes a long series of important experiments carried out chiefly by Prof. Hummel. Prof. Armstrong opened a discussion on laws of substitution, especially in benzenoid compounds, in which the conditions of substitution in amines and phenols were dealt with. The course of the reaction in those cases in which ortho- and para-compounds, on the one hand, and essentially meta-compounds, on the other, result were discussed, and the possibility of the formation of intermediate products in the former case which subsequently undergo isomeric change fully considered. Prof. Armstrong also contributed papers on the relative orienting power of chlorine and bromine, and on isomorphism in benzene sulphonic derivatives. Extremely interesting isomorphous relations have been observed amongst these latter compounds, and a committee was appointed by the Section for their further investigation. Mr. Fenton read a summary of his researches on oxidation in presence of iron, in which the extension of his reaction to tartronic, lactic, glyceric and malic acids was referred to, and, in conjunction with Mr. Jackson, described the condensation products obtained from glycollic aldehyde under the influence of dilute alkali. $\beta$-Acrose appears to be formed when a 1 per cent. solution of caustic soda is used, whilst a starch-like product results when the aldehyde is heated to $160^{\circ}$–$170^{\circ}$. Messrs. Morrell and Crofts gave an account of further experiments on the action of hydrogen peroxide on carbohydrates in presence of iron salts, the most interesting result obtained being the formation of a dibasic six-carbon atom acid from glucosone. Special interest centred in a paper by Mr. W. J. Pope on the influence of solvents on the optical activity of organic compounds, in which he traced the variations in the specific rotation of an optically active substance dissolved in various solvents to the degree of association of the active compound, and on this association factor founded a method for determining whether a particular optically active substance forms a liquid racemic compound with its optical antipode. Mr. Pope also described a new method for resolving racemic oximes into their optically active components, and Dr. M. O. Forster gave an interesting account of his researches on the influence of substitution on optical activity in the bornylamine series. Dr. Forster also described some new derivatives of camphoroxime, the chief interest of which lies in their relation to certain oxidation products of camphor. Dr. C. A. Kohn and Dr. W. Trantom, in a paper on the action of caustic soda on benzaldehyde, showed that, in the absence of water or in the presence of an excess of aldehyde, benzyl-benzoate is formed as a product of the decomposition; its production points to the formation of an intermediate ortho-compound in the reaction commonly employed in the preparation of benzyl alcohol. Prof. Emerson Reynolds described some new silicon compounds obtained by the action of ethyl mustard oil on silico-phenyl-di-imide, and Prof. Ladenburg read a summary entitled "The development of chemistry in the last fifteen years," in which the advances of the various branches of the science during that period were dealt with. Of more general interest was a paper by Prof. Clowes on intermittent bacterial treatment of raw sewage in coke beds, which was followed by one by Mr. W. Scott-Moncrieff on the place of nitrates in the biolysis of sewage. Both papers, as well as the report of the committee on water and sewage examination results, led to an interesting and useful discussion. In a paper on the chemical effect on agricultural soils of the salt-water flood of November 29, 1897, on the East Coast, by Messrs. T. S. Dymond and F. Hughes, the remarkable result was recorded that although the proportion of salt left on the soil was insufficient to prove injurious to the growing crops, the earth-worms in the soil were entirely removed, with the consequence that very few crops were worth harvesting the following year. This year nine-tenths of the salt originally present has disappeared from the soil, and young worms have again made their appearance, but still the condition of the soil remains unsatisfactory, the rate of percolation of water through the flooded soil being only half as rapid as through the unflooded. This the authors trace to the action of the chlorides of the sea water on the double silicates of the soil with the formation of silicate of alumina in a gelatinous condition,

## GEOLOGY AT THE BRITISH ASSOCIATION.

ABANDONING on this occasion the customary procedure of opening the proceedings with the presidential address, Section C plunged at the first meeting into the midst of its work with a long list of papers. The reason for this change was that Sir Archibald Geikie's address might be heard on Saturday by the visiting members of the French Association between their reception in the Town Hall and their entertainment at luncheon in the College Close. The arrangement proved highly successful, and the President's eloquent demand that geologists should be allowed to investigate the duration of geological time for themselves with data at their command, unhampered by the vague speculations in which the physicists have indulged, was listened to by a crowded audience, the platform being occupied by a distinguished group of British and foreign men of science.

As befitted their importance and local interest, the first papers taken on Thursday were those relating to Coal-exploration in Kent. Mr. R. Etheridge dealt at some length with the relations between the Dover and Franco-Belgian Coal-basins, without, however, adding much new information to what is already known. Prof. W. Boyd Dawkins, after once more reviewing the history of the discovery, gave some valuable data respecting the boring carried on under his supervision at Ropersole, eight miles north-west of Dover, where Coal-measures have been struck at a depth of 1580 feet, after Chalk, Gault, Lower Greensand, Wealden, Corallian, Oxfordian, Bathonian and Liassic strata had been passed through, and respecting other borings at Ottinge, Hothfield, Old Soar near Tonbridge and Penshurst, of which the first, at a depth of 730 feet, is in Kimeridge Clay; the second, at 800 feet, in Portlandian beds; the third, at over 700 feet, in Hastings Sands; and the last, at 1867 feet, in Kimeridge Clay. From these data, Prof. Dawkins concludes that the southern boundary of the concealed coal-basin ranges under the southern scarp of the North Downs for some distance to the westward of Dover, along the line marked by the Pembroke-Mendip anticline, and that to the south of this anticline the Palæozoic floor is probably composed of pre-Coal-Measure rocks.

The discussion elicited by these two papers was scarcely worthy of the subject, perhaps from the matter having lost its freshness through so much having been written upon it.

At the same meeting Mr. W. Gibson, of H.M. Geological Survey, contributed a short account of the results of his investigations among the Upper Carboniferous rocks of North Staffordshire, which have an important bearing upon the question of the coal-fields lying concealed beneath the Red Rocks of the Midland counties. Mr. Gibson showed that considerable areas of so-called Permian rocks in the region which he has examined are conformable to the Upper Carboniferous strata and cannot be separated from them. By working out the details of these strata he has been able to detect true Upper Coal-Measures farther westward than has hitherto been done, and has found evidence that on the north-west side of the North Staffordshire anticline the valuable coal-measures and ironstones do not uninterruptedly descend beneath the so-called Permian, but rise locally westward and are nearer the surface than might have been expected.

Another paper of stratigraphical interest was that of Mr. A. J. Jukes-Browne on a recent boring through the Chalk and Gault near Dieppe, which shows that the Folkestone and Wissant facies of the Gault extend southward as far as Dieppe, a distance of about fifty-two miles.

Owing to the lantern being available on two days only during the meeting, viz. on Friday and Monday, it became necessary to take all papers requiring this method of illustration on these days, and the usual grouping of the contributions according to subject was, in consequence, only partially possible. At Friday's session Dr. A. W. Rowe gave an account of the methods by which he has attained such magnificent results in the photomicrography of opaque objects, illustrating his address by a representative series of views to demonstrate the value of this mode of research in the study of the minute structure of fossils. Dr. G. Abbott then discussed the formation of concretions; and Dr. H. J. Johnston-Lavis dealt with that thorny question the origin of oolitic structure, renewing the debate begun last year at Bristol and strongly combating Mr. Wethered's view that the structure was originally organic. Unfortunately, Mr. Wethered was not present to sustain his case, but there was nevertheless an instructive discussion. Prof. W. J. Sollas in a short note on a cognate subject, the origin of flint, stated that he had recently found the hollow casts of sponge-spicules in abundance in the chalk in the vicinity of bands of flint both in Oxfordshire and on the Kentish coast, thus sustaining the view that the silica of the nodules was derived from this source.

Mr. E. Greenly described at this session some remarkable funnel-shaped pipes of hard sandstone in the Carboniferous Limestone of Dwlbau Point, East Anglesey, due to contemporaneous erosion of an exceptional kind; and he also gave an account of the glacial phenomena of the same locality. Prof. P. F. Kendall had an excellent paper on extra-morainic drainage in Yorkshire, in which he claimed that numerous abnormal valleys in the Eastern Moorlands and in the hills west of the Vale of York must have been excavated by the drainage of lakes formed at the margin of the ice-sheet during the glacial period; and Mr. J. Lomas put forward some new ideas respecting the formation of lateral moraines and rock-trains in glaciers.

On Saturday, as already mentioned, the president delivered his address, which constituted the only business of the Section.

On Monday a long list of papers was taken, including several with lantern illustration. Prof. Sollas discussed Homotaxy and Contemporaneity, showing that Huxley's well-known contention could not be sustained and had led to much misunderstanding of the value of fossil evidence. Prof. W. W. Watts briefly described a smoothed and grooved surface of Mount Sorrel Granite underlying undisturbed Keuper Marl, and his paper led to one of the best discussions of the meeting as to the climatal conditions of Triassic times, most of the speakers agreeing that the surface in question had probably been worn by wind-driven sand, and that it afforded further evidence of desert conditions during the period. Another short paper of high importance was that of Prof. A. Renard on the origin of Chondritic Meteorites, in which it was shown that the rock-structure of certain of these extra-terrestrial fragments presented the familiar phenomena of dynamo-metamorphism. As the president remarked in the discussion, it is not often that the geologist can apply the principles of his science beyond the sphere he inhabits.

The local effects of coast-erosion were next described and well illustrated by Captain McDakin and Mr. G. Dowker, after which Mr. W. Whitaker presented the first fruits of the efforts recently made by the Council of the Association to obtain from the coastguards all round our shores, with the sanction of the Lords of the Admiralty, schedules of information as to the changes due to the action of the sea.

Mr. Vaughan Cornish then exhibited a series of photographs of Wave-phenomena, and discussed the relations between wave-forms in different substances, a discussion which was renewed at a later session. The eruption of Vesuvius in 1898 was described and illustrated by Dr. Tempest Anderson; while Prof. G. Platania contributed an account of the recent volcanic phenomena of Mount Etna; and an excellent day's work was concluded by a report by Prof. P. F. Kendall on the results obtained by a local committee, by the use of chemical reagents, as to the flow of underground waters in the limestone district of Craven in Yorkshire at the sources of the Aire. A committee of the Association was formed to continue these researches, and a grant of 50*l*. was obtained in aid of the expenses.

The first paper taken on Tuesday was that of Prof. W. Boyd Dawkins on the geology of the Channel Tunnel, in which, after indicating the conditions under which the proposed tunnel would have been made, it was stated that in the portion 2300 yards long already excavated on the English side, the Lower Grey Chalk was soft enough to be easily cut by machine and hard enough to stand without lining, and that five years' exposure had not sensibly affected its cut surface. It was generally conceded by the speakers in the subsequent discussion that the geological conditions were peculiarly favourable for the construction of the tunnel, and that, apart from the political question, no insuperable difficulty was likely to be encountered.

Mr. F. W. Harmer then read a carefully prepared paper on a proposed new classification of the Pliocene deposits of the east of England, in which he suggested the terms *Lenhamian* for the Lenham Beds, *Gedgravian* for the Coralline Crag, *Waltonian*, *Newbournian* and *Butleyan* for different portions of the Red Crag, *Icenian* for the Norwich Crag, and *Chillesfordian* and *Weybournian* respectively for the Chillesford and Weybourne deposits. The author considers the Red Crag to have accumulated in shallow inlets which were silted up one after another during a slow upheaval of the southern part of the area. In a

second paper Mr. Harmer discussed the meteorological conditions of North-western Europe during the Pliocene and Glacial periods, finding in the early glaciation of Scandinavia, and the consequent establishment of anticyclonic conditions over that area, a probable solution of the change in the direction of the prevalent winds which he believes to be necessary to account for the accumulation of the crag-deposits on our eastern coast.

A short paper by Rev. J. M. Mello on some palæolithic implements of North Kent, and the exhibition on behalf of Mr. B. Harrison of a collection of "eoliths" from the neighbourhood of Ightham, led to a brisk discussion, in which Sir John Evans, Prof. Boyd Dawkins and other speakers denied that the so-called "eolithic implements" showed proof of human workmanship, while Prof. T. Rupert Jones stated Mr. Harrison's view of the case and was supported by Mr. Allen Brown.

The chief paper of the final session on Wednesday was that of Mrs. M. M. (Ogilvie) Gordon on sigmoidal curves in the earth's crust. This admirably rendered discourse was supplementary to the work recently published by Mrs. Gordon in the *Quarterly Journal of the Geological Society* and in NATURE, and had for its object the general statement of the phenomena which are presented when rock-folds in two directions intersect each other and produce "crust-torsion," with particular reference to the earth-forms which have been thus produced in the Alpine mountain-system. The complexity of the subject seemed to daunt most of the speakers in the discussion; but Prof. Lapworth pointed out how well the results of Mrs. Gordon's field-work agreed with the theoretical deductions to be drawn from the study of intercrossing earth-waves.

As usual, some of the most solid work of the Section was embodied in the reports of the committees of research which were presented during the meeting, but of which lack of space forbids more than the bare mention. Among these were the reports presented by Prof. A. P. Coleman on Interglacial Beds in Canada; by Mr. P. M. C. Kermode on the Deposits containing Elk remains in the Isle of Man; by Prof. P. F. Kendall on Erratic Blocks; by Rev. G. C. H. Pollen on the Ty Newydd Caves; by Mr. H. Bolton on the Uphill Caves; and by Prof. W. W. Watts on Geological Photographs.

Short afternoon excursions, which have become an established feature of the Section's arrangements, were made during the week to the Ropersole Coal Boring, to the colliery works under Shakespeare Cliff, to the East Cliff and St. Margaret Bay, and to the Warren at Folkestone.

To sum up the proceedings of the week—the sessions of the Section were well attended throughout, and the papers, though without any especially salient features, maintained a good average both in numbers and quality. Some palæontological papers which might have found place in the Section were taken in Sections D and K, and this branch of geological science was in consequence scantily represented in the list.

## UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Mr. W. L. H. Duckworth has been appointed to the University lectureship in physical anthropology.

Mr. R. G. K. Lempfert has been appointed Assistant Demonstrator in Experimental Physics.

It is proposed that McGill University, Montreal, be adopted as an institution affiliated to the University.

A NEW technical institute is to be erected, at a cost of 8450*l.*, in Carisbrooke Road, Liverpool.

THE sum of 25,000 dollars has been promised to Vassar College towards a biological laboratory on condition that an equal amount be raised for the same purpose by other means.

THE foundation-stone of a new technical college for Sunderland has just been laid. The college is to cost 25,000*l.*, and will, it is hoped, eventually be affiliated to Durham University.

DR. C. B. DAVENPORT, of Harvard University, has been appointed professor of zoology at the University of Chicago, in the place of Prof. Wheeler, who has gone to the University of Texas.

MR. H. B. KNOWLES has been appointed principal of the Swindon and North Wilts Technical School. Hitherto he has been teacher of physics and electrical engineering at the Bradford Technical School.

THE Technical Instruction Committee of the West Riding (Yorks.) County Council have consented to financially assist the managers of the district technical schools in forming reference libraries on the subjects of local instruction.

MR. EMERSON E. MCMILLIN has given the Ohio Academy of Science 250 dollars with which to carry on scientific investigations, and declared his intention of giving a similar amount annually if the money is wisely expended.

DARTMOUTH (U.S.A.) COLLEGE has recently received from Mr. E. Tuck, of New York, 300,000 dollars, to be used for the purposes of instruction, and Tuft's College has had bequeathed to it the sum of 60,000 dollars by the late Mrs. M. D. Goddard, of Newton, Mass.

THE regents of the University of California have accepted the plans designed by M. Bénard, of Paris, for their new university buildings, and some of the buildings will, it is stated, be begun next spring. The movement, as will be remembered, is mainly due to the generosity of Mrs. Phœbe A. Hearst.

AT a meeting held at Newcastle on Monday last, it was decided to make an effort to raise funds for the completion of the buildings in connection with the Durham University College of Science. Subscriptions amounting to 9500*l.* were promised at the meeting, and the sum of 100,000*l.* will, it is hoped, be raised by the end of the year.

IN connection with the Liverpool University College, Mr. W. Rathbone has made provision for the award annually of a Rathbone medal to the most distinguished third-year student. Mrs. George Holt and Miss Emma Holt (to whom the College has on more than one former occasion been much indebted) have each given the sum of 5000*l.* towards the physical laboratories of the institution.

AMONG recent appointments abroad we notice the following:—Dr. S. Avery to be professor of chemistry in the University of Idaho; Mr. H. B. Ward to be professor of zoology at Nebraska University; Mr. P. Field to be professor of mathematics in Carthage College; Dr. E. O. Sisson to be director of the histological laboratory in the recently consolidated medical schools of Keoduk, Iowa.

WITH reference to a recent note in this column respecting the admission of women students to the course of study at the Owens College which would qualify them for medical degrees and practice, we are requested to state that the resolution in favour of the course adopted was carried by a majority of nineteen, the voting being twenty-one for the resolution and two against it.

THE promoters of the Birmingham University scheme have recently received the munificent donation of 20,000*l.* from Mr. Charles Holcroft, and a number of large sums from other gentlemen, which bring the total amount promised to upwards of 315,400*l.* The total of over 300,000*l.* having been reached, the committee have secured the last 12,500*l.* which was offered by the friend of Mr. Joseph Chamberlain who prefers to remain anonymous.

## SCIENTIFIC SERIAL.

*American Journal of Science*, October.—Explosive effect of electrical discharges, by J. Trowbridge, T. C. McKay, and J. C. Howe. The authors investigated the sudden increase of pressure in the gas, through which the discharge passes, by means of a vacuum tube provided with a manometer gauge. When spark-gaps up to 50 cm. were employed, with a maximum difference of potential of three million volts, they found that the explosive effect increased closely in proportion to the length of the spark, and began to diminish when the spark was longer than 50 cm. The air itself then becomes a fairly good conductor, and is strongly ionised.—Colour vision and the flicker photometer, by O. N. Rood. The author's flicker photometer reveals the fact that the curve of colour vision is not the same in any two persons supposed to have normal sight. Among five persons capable of sustaining Holmgren's worsted test, differences of colour values ranging from 1 to 14 per cent. were found.—Iodometric determination of gold, by F. A. Gooch and F. H. Morley. The authors investigate the effect upon the immediate evolution of iodine brought about by adding varying amounts of water to the gold solution before introducing the

iodide, and the effect of different amounts of iodide at different dilutions.—Mineralogical structure and chemical composition of the Trap of Rocky Hill, N.J., by A. H. Phillips. The Rocky Hill trap, from its holocrystalline nature, would be classed as a dolerite. From the character of the decomposition of the olivine, and the solution cavities in the diallage crystals, the intrusive nature of this dike is evident, as it must have been formed at a considerable depth below the surface and under very heavy pressure.—Some analyses of Italian volcanic rocks, by H. S. Washington. This paper deals with the composition of trachytes of the Phlegrean Fields and of Ischia. There are three parallel volcanic lines in the Italian district. The latest, along the peninsula, is characterised chiefly by high $K_2O$, by high CaO, and the presence of leucite. The next, that of the islands along the west coast, is high in alkalis, but with $Na_2O$ rather higher than $K_2O$, and without leucite. The third, which lies far out in the Mediterranean, and which is possibly the oldest, is much higher in soda, and seems to be characterised by the presence of peculiar soda minerals such as enigmatite and ægirine, nepheline also occurring in places.—Thermo-electricity in certain metals, by L. Holborn and A. L. Day. This is an English version of the author's Reichsanstalt paper on the gas thermometer.

## SOCIETIES AND ACADEMIES.

### PARIS.

Academy of Sciences, October 9.—M. van Tieghem in the chair.—On the elastic equilibrium of a rectangular plate, by M. Maurice Lévy.—Some remarks on double integrals of the second species in the theory of algebraic surfaces, by M. Émile Picard.—On a modification of Bessel's method for calculating occultations, by M. L. Cruls. In the modification suggested use is made of the time of apparent conjunction of the two stars. The advantage resulting from this method is twofold: it gives by a single calculation a precision generally only obtainable by a second approximation, and lends itself easily to a graphical construction and a simple geometrical interpretation of the different elements upon which the conditions of the phenomenon depend.—Observations of the Giacobini Comet (1889 *e*) made at the Observatory of Besançon, by M. P. Chofardet. The observations were made on the nights of October 3 and 4 The comet had the appearance of a nebulous sphere, 1′ in diameter, and having a slight nucleus of about the 13th magnitude.—On fundamental functions and on the development of a holomorphic function at the interior of a contour in a series of fundamental functions, by M. Renaux.—On the stereochemistry of nitrogen, by M. J. A. Le Bel. The author replies to various criticisms by van 't Hoff, Markwald and others on his work published in 1891 on the preparation of active compounds from methyl- ethyl- propyl-isobutylammonium chloride, and lays down the exact experimental conditions necessary to repeat his results. The conclusion is drawn that there can now be no doubt as to the optical isomerism existing in the derivatives of ammonium chloride containing four different radicles, and containing at least ten atoms of carbon. It is also established that with derivatives less rich in carbon the stability of these optical isomerides is diminished.—On the reversible liquefaction of albuminoids, by M. Tsvett. It is known that the solution of albuminoids is favoured by certain acids, alkalis, and salts. The author has found that certain organic substances, such as resorcinol, pyrocatechol, phenol, chloral hydrate, &c., possess this liquefying property to a very marked extent. Thus a solution of gelatine treated with an eighty per cent. aqueous solution of resorcinol, forms two liquid layers, the upper a solution of gelatine in aqueous resorcinol, the lower a solution of aqueous resorcinol in gelatine, the coefficients of reciprocal solubility varying with the concentration of the resorcinol and the temperature. The phenomenon appears to be truly reversible.—On the volumetric estimation of quinones derived from benzene, by M. Amand Valeur. The quinones are reduced by a mixture of potassium iodide and hydrochloric acid, and the liberated iodine titrated with sodium thiosulphate. Experiments were carried out with quinone, dichloroquinone, toluquinone, and thymoquinone; the results are quite satisfactory, and are very rapidly obtained.—On the structure of the nucleus in the myelocytes of Gasteropods and Annelids, by M. Joannes Chatin. The myelocytes of these invertebrates, contrary to the usual statements, may show a very clear, nuclear membrane.—On the alternation of generations in *Cutleria*, by M. C. Sauvageau.—On a gutta-percha plant capable of being cultivated in a temperate climate, by MM. Dybowski and G. Fron. The authors have extracted gutta-percha from the fresh leaves of *Eucomia ulmoides*. This plant can be grown in temperate climates, and experiments were carried out as to the best mode of multiplication of the plant. It is easy to obtain good seeds in large quantity, but their germination is difficult and capricious. Propagation through cuttings, however, offers no difficulties, the slips taking root easily and developing vigorously.—Action of anæsthetic vapours upon the vitality of dry and moist seeds, by M. Henri Coupin. The vitality of dry seeds is unaffected even by saturated ether and chloroform vapours; but with moist seeds the case is quite different, the presence of only 3·7 c.c. of ether in 10 litres of air being sufficient to kill the seed.

## DIARY OF SOCIETIES.

THURSDAY, OCTOBER 26, 1899.

## THE INTERNATIONAL ASSOCIATION OF ACADEMIES.

OF late there has been much activity in matters which require the co-operation of scientific men of different nationalities. The International Catalogue of Scientific Literature has been the subject of several conferences. The International Meteorological Conference and the Bureau International des Poids et Mésures are samples of different types of organisations which are both numerous and useful.

The exchange of courtesies at Dover between the British and French Associations for the Advancement of Science gave another proof that cosmopolitanism is growing in strength in the scientific world, and can assert itself even when the political atmosphere is not unclouded.

A still more striking instance of the same fact will be found in the account which we give in another column of a conference at which the possibility of founding an International Association of the great Academies of the world was discussed by their representatives.

The details of the plan are, we believe, still under consideration, but enough has been done to make it practically certain that the Association will be founded, and that the Royal Society, the Academies of Science of France, of Berlin, St. Petersburg, Vienna, Rome, Washington and other similar bodies will be brought into formal relations with each other. It is, no doubt, open to pessimists to say that international meetings are now too numerous, but we venture to think that the proposal to bring about formal conferences between the principal scientific bodies in the world is most important, and that the meetings are likely to lead to more permanent results than do gatherings (also useful in their way) from which the picnic element is not altogether eliminated.

On the other hand, an Association of Academies will be a more flexible instrument for good than are international organisations appointed for specific purposes, and composed either of persons named by the Governments of the countries represented, or of officials controlling national observatories.

The Committee of the Bureau International des Poids et Mésures in Paris and the Geodetic Conference at Berlin are examples of bodies which are entrusted with strictly defined duties, and cannot travel outside the lines laid down for them by their respective Governments. A union of Academies would, however, bring about the meeting at stated intervals of representatives of science, who would not be fettered by the official ties which must necessarily restrict the action of Government nominees. It would thus be possible for the associated Academies to discuss questions connected with any branch of science which might in their opinion call for international co-operation, and if they decided that such action was desirable, to take steps to call the attention of the scientific world or of the various Governments to the necessity for united action.

The Association would, in fact, enjoy the same freedom as the Council of the Royal Society, while it would be able to bring to bear on any question the mature opinion of representatives of the whole scientific world.

It is obvious that an Institution founded on these lines may become of the very first importance, and may play the part of an international parliament of science. Whether or no such a hopeful forecast is realised, it cannot but be useful that the centres of scientific organisation in different countries should themselves be organised, and should be united—not merely by common interests, or by the bonds of friendship which have been established between many of their members—but by formal links which will enable them to take united action when such action is required.

As some of the foreign Academies are concerned with literature and philosophy as well as with natural science the Association will be based upon the same lines. The two sections into which it will be divided will, however, be almost entirely independent, and no serious difficulty need be anticipated on this score. It is, however, curious that though both of the great Anglo-Saxon nations possess important societies concerned with the cultivation of different branches of literature, history or philosophy, neither of them has developed an institution the breadth of whose aims would warrant its inclusion in a list of Academies of literature. It will be unfortunate if this fact makes the literary section of the new Association less truly representative than that which will be concerned with natural science.

"An academy quite like the French Academy . . . we shall hardly have, and perhaps we ought not to wish to have it," said Matthew Arnold, but it will be interesting to see if the foundation of an International Association of Academies leads to a rearrangement of existing organisations which might give us in England something corresponding to the "Académie des Inscriptions et Belles-Lettres," or to the "Académie des Sciences Morales et Politiques."

## A PIONEER IN TELEGRAPHY.

*The Life Story of the late Sir Charles Tilston Bright; with which is incorporated the Story of the Atlantic Cable and the First Telegraph to India and the Colonies.* By his Brother, Edward Brailsford Bright, and his Son, Charles Bright. Pp. xix + 506, and xi + 701. (Westminster: A. Constable and Co.)

TWO books have recently appeared dealing with telegraphy from shore to shore, the one on "Submarine Telegraphs" from the pen of Mr. Charles Bright alone, the other the two-volume treatise now under review. Both are somewhat lengthy, the former because the description of "Submarine Telegraphs" was so much bound up with details concerning the life of Sir Charles Bright, and the latter because to the "Life Story of the late Sir Charles Bright" has been added so much about the history of submarine telegraphy.

Leaving the accounts of the ancestors of this family which are given in rather bewildering detail, we come to the boyhood and youth of the two brothers Charles and Edward. Charles at fifteen, and Edward at sixteen, entered the service of the Electric Telegraph Company soon after its formation in 1847, and started on their careers as inventors. In 1849 they devised a method

for enabling the position of a fault on a telegraph line to be ascertained electrically by the use of resistance coils. In two more years they both left the Electric Telegraph Company, and joined other companies which had started as rivals of this company and of one another, viz. the British Telegraph Company, to which Charles became the assistant engineer, and the Magnetic Telegraph Company, with which Edward associated himself.

But it was the ingenuity and energy which the subject of this memoir displayed in laying the telegraph wires under the streets of Manchester that first brought him into prominent notice. In one night the many gangs of navvies under his superintendence had the streets up, the lower halves of cast iron tubes laid down, gutta-percha covered telegraph wires (wrapped into ropes with tarred yarn) unwound off drums into this iron channel, the two halves of the tubes placed in position, the trench filled up, and the pavement laid down before the inhabitants were out of their beds in the morning.

This account reads like that of a cutting-out expedition of a young Nelson, or a surprise attack of a youthful Wellington, and such an exploit hardly seems possible in the case of the County Council scholar of the modern day, full, it is true, of facts and knowledge, but who has devoted so much attention to learning off what other people have thought out, that he has never had time to find out what he thinks himself, and the bent of whose activity seems to be directed to begging his numerous teachers to give him a sheaf of testimonials and to furnish him with a post.

We can also recommend the study of this exploit of the nineteen-year old Bright to the notice of the local authorities of London from another point of view. In entire oblivion apparently of the fact that the traffic in our streets is not only as great as it was half a century ago, but has become one of the most perplexing difficulties of the present time, and probably in ignorance also of the fact that the developments that have taken place during the past ten years in electric lighting have supplied facilities for carrying on night work in the streets such as were not dreamt of fifty years ago, Bumble still lays long lines of pipes under Fleet Street, Holborn, and the Strand, on what may be called the one man, one boy and a donkey-cart method. And further, since it is generally during the height of the London season that the streets remain broken up for days at a time, we presume that the local authorities are labouring under some delusion that the navvy periodically spends his autumn away from town—say in Switzerland—and is, therefore, only available as an obstructionist about the month of May.

The cable to Ireland having been successfully laid in 1853, attention began to be turned to connecting Great Britain with America. The Atlantic Telegraph Company was consequently formed, but without advertisements or a board of directors, without brokers, commissions, executive officers, promotion money, or even a prospectus. What a striking contrast to the present philanthropic efforts of the "vendor" to benefit the world, and the anxiety of the "scientific expert" to give wide publicity to the extraordinary efficiency of everything that is brought to his notice—professionally.

Considerable vagueness existed at that period as to what the speed of sending messages through a submarine cable really depended on; the memoir states that Sir Charles Bright advocated the employment of a thick copper conductor, weighing $3\frac{1}{2}$ cwt. per mile, surrounded by a coating of gutta-percha having the same weight, but that Faraday, Morse and Whitehouse did not understand the problem properly, and therefore that they opposed Bright's proposal to use a large conductor for the reason that the electric capacity of the cable would be thereby made large, and as, therefore, a large amount of electricity would be required to charge it at each signal the speed would be slow. Lord Kelvin in his Royal Society paper pointed out that the retardation depended neither on the capacity alone nor on the resistance of the conductor alone, but on the product of the two; and so made the whole theory clear—at least made it clear to those who were able to appreciate what a Fourier series could possibly have to do with telegraphing to America.

But economical counsels prevailed, and the copper conductor of the actual Atlantic cable weighed only 107 lbs. a mile, and the gutta-percha coating 261.

The account of the laying of the first Atlantic cable is stirring, thanks partly to the long extracts from the graphic and exciting descriptions which were published by Mr. Nicholas Woods in the *Times*. Numerous were the attempts to lay this cable, and, although they were at last crowned with success—in so far that an Atlantic cable was completed in August 1858, and several messages were actually sent through it—this cable had but a very brief life, one of only three short months in fact.

Numerous arguments are adduced to prove that the causes which led to its break-down all arose from one reason, viz. that the directors did not take the advice of Sir Charles Bright. But, although it is undoubtedly true that the subject of the memoir was an exceptionally able, enthusiastic and energetic man, the contention that if only his advice had been followed the 1858 Atlantic cable would have been a permanent success is not quite so obvious.

For example the use of a powerful induction coil to work a long cable, which is so properly denounced in the body of the book itself, and to which the speedy death of the first Atlantic cable was undoubtedly, at any rate in part, due, was actually resorted to by Sir Charles in his experiments on ten separate lengths of underground wire, joined up to make a total length of two thousand miles, as described in his remarks at the Institution of Civil Engineers in 1857, and quoted in Appendix v. of the book under review. And the successful results obtained with these induction coils "thirty-six inches in length and excited by a powerful Grove battery of fifty pint cells," were advanced as a reason why "he could not see what there was to prevent the working, successfully, through a direct line of two thousand miles" such as an Atlantic cable.

Again, the folly of the Atlantic Telegraph Company in not adopting the larger dimensions which Sir Charles Bright desired to give to the first Atlantic cable is not so evident, since the 1865 cable, which possessed these dimensions, had to be abandoned—broken, after many

unsuccessful attempts had been made to lay it—and in the following year, some months after it had been recovered and completed, both it and the new 1866 cable broke, while one of them broke again the following year.

The fact is that to construct an Atlantic cable at all in those days was a very courageous thing to do; to lay it successfully, even with many failures, evinced a faith and confidence in engineering skill and a dogged spirit of determination that make one proud of the Anglo-Saxon race. To every one who took a prominent part in the enterprise, as certainly did Sir Charles Bright, all honour is due as well as the thanks, not only of his contemporaries, but of all who have followed him.

But we are inclined to think that the authors of this memoir would have been well advised had they not allowed their reverential memory for the brother of the one and the father of the other to lead them to adopt the painter's only method of representing a bright light, viz. by intentionally throwing the rest of the picture into shade.

Volume ii. deals with the telegraph to India, Sir Charles' parliamentary life, the West Indian cables, Sir Charles' work in connection with mining, fire alarms, telephony, electric lighting, the Paris Electrical Exhibition of 1881, the Institution of Electrical Engineers, Freemasonry, and concludes with various appendices.

This life-story is distinctly interesting, but its interest would have been even greater had the matter been compressed into about half, or at any rate into not more than two-thirds, the space. Before a second edition appears we would suggest that such scientific crudities as the following should be altered:—"A current which was estimated by the experts to amount to about 2000 volts." "In the absence of a determinate unit of inductive capacity or quantity of electricity condensers were employed for the first time." "When electricity passes through this surrounding coil of wire, the magnet and mirror take up a position of equilibrium between the elastic force of the silk and the deflecting force of the current. . . . The magnet is artificially brought back to zero with great precision after each signal by the use of an adjustable controlling magnet."

## OUR BOOK SHELF.

*The Maintenance of Solar Energy.* By F.R.A.S. Pp. 20. (London: The Southern Publishing Co., Ltd., 1899.)

THE author of this short essay is not satisfied with the current ideas as to the maintenance of solar energy, but believes his new views tend to remove much of the difficulty. So far as can be judged by these "preliminary notes," however, the theory advanced is one which is not likely to convince any one but its author. Interplanetary water vapour and the periodical indulgence of the sun in cometary vapour baths appear to play an important part, the idea being that as a result of their action the radiant forces of the sun are confined within the limits of the solar system. The recurring absorption of the planets by the sun and subsequent disruption into new systems are other features of a theory which has its principal strength in the fact that there are no means of testing its chief teachings. The author's name does not appear on the title-page, but the preface is signed by J. H. Brown.

*Official Report of the National Poultry Conference held at Reading in July* 1899. Edited by the Honorary Secretaries, Edward Brown, F.L.S., and F. H. Wright, F.S.A.A. Pp. xvi + 138.

THE conference of which this is a report was the first of its kind held in this country, and its success should lead to other similar meetings. The report shows that most of the papers were of a scientific character, and its publication should extend the knowledge of the principles which lead to successful poultry-farming. Among the subjects dealt with are: the science and practice of farm poultry keeping, the parasitic diseases of poultry, and the assistance afforded by science in the production of eggs and poultry. There will be hope for British agriculture when the spirit which pervades these papers guides the operations of all who are concerned with rural industries.

*The Story of Ice in the Present and Past.* By W. A. Brend. Pp. 228. (London: George Newnes, Ltd., 1899.)

AN instructive addition to the "Library of Useful Stories," containing a clearly-written account of the physical properties and geological operations of ice. General readers should find the volume interesting. We notice that the cavities formed by glacier mills are termed "potholes or giant's kettles"; but the former term ought to be restricted to the circular holes found in the beds of streams.

## LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

### Effect of Vibration on a Level Bubble.

I HAVE never seen any notice of this phenomenon, but it is sufficiently curious to be worth describing.

I had fitted on a bicycle a small level with a radius of curvature of a foot, in order to note gradients without dismounting. In general this answered very well, and the gradients could be satisfactorily measured with an accuracy of about 1 per cent., but when going over certain classes of rough road (*e.g.* granite paving), the roughnesses of which had a definite pitch, it was noticed that though the road might be level, the bubble would at certain speeds indicate gradients as steep as one in eight or one in six, and remain steadily in such positions as long as the speed and character of the road remained constant. It seemed a matter of chance whether the bubble moved so as to indicate an up or a down gradient.

The explanation is to be found in the coincidence of a natural period of the bubble, due to the surface tension of the fluid, and the interval which elapses between successive encounters of the bicycle wheel with the roughnesses of the road.

Owing to the level being at a certain height above the ground (it was attached to the upper tube of the frame), any pitching of the bicycle, such as is caused by going over rough ground, gives a backward and forward motion to the frame in addition to the general onward movement.

We may suppose, for the sake of simplicity, that this backward and forward motion is a simple harmonic.

When a level is subjected to a harmonic displacement parallel to the mean direction of the tube, the bubble will endeavour at each instant to place itself at that part of the tube where the tangent is at right angles to the resultant of gravity and the imposed acceleration. Thus the bubble tends to move relatively to the tube in the direction of the displacement of the latter, and would always occupy its true position with regard to the resultant if its motion under the variable force was quick enough. The motion of the bubble, however, is very slow compared with that required to bring about this result; but although the forces which act on the bubble have not time to move it far in each period, they do deform it, and the deformation may become

large if the imposed force has the same frequency as any of the natural vibrations of the bubble.

When the bubble is long, as in an ordinary level, the result when such a coincidence is reached is that the long bubble is broken up into a number of small ones, but in the bicycle level the bubble was small and nearly spherical.

The slowest natural vibration which a spherical bubble is capable of is that in which it becomes alternately a prolate and oblate spheroid.

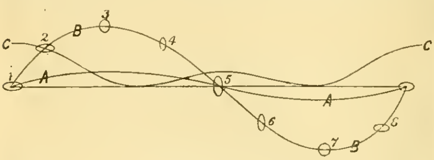
It would take too long to enter in detail into the character of the deforming forces acting on the bubble. They are of two kinds, one depending on the acceleration and the other on the velocity. The former tends to make the bubble egg-shaped (*i.e.* big at one end and small at the other) to a degree proportionate to the acceleration; the latter involves the ratio of the cross section of the bubble and tube, and tends to make the bubble oblate as the velocity increases.

When the impressed motion has the same period as the bubble, the latter will pass through its zero position in opposite phases. Thus, if in moving forwards it is an oblate spheroid as it passes through the zero, it will be prolate half a period later when returning backwards through the same position, but both the deforming force and resistance to motion through the fluid which the bubble experiences when prolate are less than when it is oblate, so that there is a balance in favour of the oblate deformation, which will tend to increase and perpetuate a vibration once started.

Since the resistance experienced by the prolate form is less than oblate resistance, the excursion of the bubble will be greater in the first case than the last, with the result that in time it will move to such a position that the slope of the tube there supplies a force sufficient to balance the difference of resistance met with in moving in opposite directions.

In the accompanying diagram the direction of the level tube is supposed to be at right angles to the abscissa axis, which represents the time of one oscillation.

AA displacement of level tube; BB displacement of bubble relatively to the tube; CC deforming force depending on the velocity; 1, 2, 3, &c., the forms assumed by the bubble at various phases.



There is some particular ratio between the diameters of the bubble and tube, and some absolute diameter of the tube, depending on the surface tension and density of the fluid, which gives the maximum displacement, but even an approximate analytical solution of the problem would present great difficulties.

In the level experimented on, the surface tension of the fluid employed was 27 (in C.G.S.) and density ·88.

The radius of the bubble was ·142 cm. and that of the tube ·23 cm. (rough measurements).

A spherical bubble of the radius given if surrounded by an unlimited quantity of fluid of this surface tension and density would have for the frequency of its slowest natural vibration 120 per second nearly (see Lamb, "Hydrodynamics," p. 463), but in the case under consideration the small distance between the sides of the bubble and tube must greatly diminish the frequency of this form of vibration.

By experiment it was found that the greatest displacement occurred with a frequency between 40 and 50 per second, the bubble then being driven to the ends of the tube where the slope was about one in five.

## Rural Education.

THE Countess of Warwick and Prof. Meldola are entitled to all praise for their zeal in establishing the School of Science at Bigods, to which reference was made in your issue of October 5. There should, however, be some recognition of the similar work done by others in purely rural districts. At Bruton, a village in Somersetshire, the success of such a school has been quite phenomenal. Sexey's Trade School, as it is called, owes its inception to Mr. Henry Hobhouse, M.P., and was founded a few years ago out of the old endowments of Sexey's Hospital under a scheme of the Charity Commissioners, with aid from the Somerset County Council. Recently I had an opportunity of seeing the school, and could not sufficiently admire the excellence of what is done there. The buildings consist of a master's house, large schoolroom and lecture-rooms, well-equipped physics and chemical laboratories, wood and metal workshops, gymnasium, &c., with about two and a half acres of garden and playground attached. Besides instruction in the ordinary subjects of a higher primary or secondary school, the boys in the upper division (Classes II. to V.) are taught magnetism, electricity, chemistry, mechanics, manual work in cardboard, wood and metal, mensuration, French, botany and bookkeeping, and the instruction in technical subjects is throughout of a *practical* nature, being given in the garden, field, and workshops, as well as in the class-room. Outdoor lessons are given in land measuring. Visits are occasionally paid to farms in the neighbourhood to inspect the stock, implements, buildings and crops. Botanical walks are taken at intervals in order to study plants in their natural habits, and the boys are encouraged to make collections of botanical and other specimens.

Since 1896 the school has been organised as a School of Science, and through the courtesy of the headmaster, Mr. Knight, I am able to place the following details before your readers. The fees for tuition are 4*l.* and for boarding 20*l.* per annum. The school has been accepted by the Somerset and Wilts County Councils as one of those at which junior and intermediate county scholars may attend. There are 103 boys at the school, of whom 25 are the sons of farmers, 20 of artizans, and 32 of small tradesmen. Of those who have left the school 34 have taken to farming as an occupation. From the forty-fifth Report of the Science and Art Department it appears that in 1897 the school presented 63 pupils for examination. The grant earned was 384*l.*, being an average of 6*l.* 2*s.* per head. The High School at Middlesbrough stood next on the list with an average of 5*l.* 13*s.* per head, and the general average for the 143 organised Science Schools in Great Britain was 3*l.* 9*s.* 6*d.* Such an experience as this ought to be of the greatest encouragement to those who are really anxious for the improvement of rural education, and the facts cannot be too widely known. This school differs from the one at Bigods in that it is only for boys; but a school is now being erected in the immediate neighbourhood to provide a modern education for girls, corresponding as far as possible with that provided for the boys.

JOHN C. MEDD.

Stratton, near Cirencester, October 15.

THE good work being done at Sexey's Trade School is of course well known to all who have interested themselves in rural education. Readers of NATURE will no doubt be glad to have Mr. Medd's independent testimony, and more particularly the detailed statement of figures concerning grants and fees. At the present time, when the subject of rural education is so very much before the public, it would, however, be of the greatest assistance to those who are engaged in carrying on this work if Mr. Medd could supply more detailed information concerning the aid which the County Council has given and how this assistance has been rendered; whether in the form of grants for building and equipment or for maintenance of staff, or both. Also what proportion of the initial cost of foundation as a School of Science was contributed by the Somersetshire County Council? In the present state of rural education one cannot help feeling that the whole future success of these schools is very largely dependent on the constitution of the Technical Instruction Committees of the County Councils—especially in those cases where the County Council has become recognised as the central authority. Any information, therefore, that can be given on these administrative points, either with respect to Sexey's or any similarly constituted school, would be most opportune. In the case of our school at Bigods, the initial cost of foundation and conversion into a School of Science has been mainly borne by Lady Warwick. The Essex County Council, as regards maintenance of staff, have put us on the same footing as the endowed schools in the county by granting 100*l.* annually.

R. MELDOLA.

## *ON THE DISTRIBUTION OF THE VARIOUS CHEMICAL GROUPS OF STARS.*[1]

SOME few years ago it was my duty to give a course of lectures here relating to the sun's place in nature. I attempted to give an idea of the relation of the sun, as to age and temperature, to other stars, and also its relation to bodies supposed to be of a different order altogether.

Since that lecture was delivered our knowledge on this and allied subjects has advanced with giant strides. We now know, thanks to spectrum analysis, the principles of which I then explained, a great deal of the chemistry of the stars, so much that we can now classify them into groups, defining those groups by the chemical elements involved in each. I shall not bring before you to-night the detailed classification of these bodies, but shall, for the purposes of this lecture, ask you to consider the four following kinds only:

*Highest temperature.*

Gaseous stars { Proto-hydrogen stars.
Cleveite-gas stars.

Proto-metallic stars.

Metallic stars.

Stars with fluted spectra.

*Lowest temperature.*

The table almost explains itself: I may add that by "proto-metallic" stars I mean those stars in the spectra of which the metals we know here are chiefly represented by lines—the so-called "enhanced-lines"—we can only obtain here by using high-tension electricity, and there are other evidences which show that these stars are hotter than the metallic ones, while they, in their turn, are cooler than the gaseous stars. In discussing the work of other observers I have as far as possible transposed the different notations employed into the chemical one given above.

In relation to the sun's place we had a great many comparisons to make with different stars quite independently of their position in space. I propose now to touch upon a still more general inquiry to consider the distribution of all stars in space, not in relation to their magnitudes, but in relation to their chemistry.

It is obvious that we are among the first from the beginning of the world who have been able to do this, because formerly the chemistry of these celestial bodies was entirely lacking. I think, therefore, you will agree that it is a very important thing, now that we have the chemistry, to inquire into the distribution of the various chemical conditions in the different parts of the universe in which our lot is cast. For that purpose, I will deal with the stars as generally as I can, considering only the wider division into the gaseous stars, the proto-metallic stars, that is to say, the stars represented by the enhanced lines, then the metallic stars in which we are dealing with arc lines, and then the metallic fluting stars and the carbon fluting stars. As star-life begins with nebula and meteoritic swarms, it ends with dark stars which it is possible may be very numerous in space. How many there are we do not know, because we cannot see them; but there are reasons for supposing that there is a very considerable number.

We have only to deal with the masses of matter in space which are visible, and it is obvious that any inquiry into the distribution of the chemical conditionings, as revealed by spectra, of these masses must be preceded by an inquiry into the distribution of these masses considered merely as masses and quite independent of chemistry.

This work has already occupied the attention of many eminent astronomers, and I will begin by placing the results of their labours before you as shortly as I can.

I call your attention to the Milky Way. If you have seen the Milky Way from a high mountainous country, as I have done, you will acknowledge what a very wonderful

FIG. 1.—Photograph of a glass globe showing the relation of the Milky Way to the Equator an to Gould's belt of stars.

thing it is; I was most struck with the Milky Way when I was in the Rocky Mountains some years ago. It was not merely the pale milky belt we generally see running across the sky, but it had lights, shades, shadows, brightnesses and dimnesses; it was full of the most marvellous details. I have seen it, I am bound to say, just as well on the coast of Kent, but not often. You want an extremely fine sky to see the Milky Way properly; but, at all events, whether you have seen it well or ill, all of you, I am sure, are familiar more or less with it. What is it? It is a bright belt encircling the heavens; its position with regard to the equator of the earth, and the equatorial plane extended to the stars, I can show you roughly by means of a glass globe. Those who are familiar with Dante know that the old view of the heavens was that the earth was immovable in the

[1] A Lecture to Working Men, delivered at the Museum of Practical Geology, on April 10, by Prof. Sir Norman Lockyer, K.C.B., F.R.S.

centre; that there were several heavens round it: the heaven of the moon, the heaven of Venus, of Mars, and so on, till at last there was a heaven of the stars, a crystalline sphere to which the stars were fixed like golden nails. Let the glass globe represent this crystalline sphere.

The Milky Way is a great circle inclined, at an angle of about 62°, to the earth's equator or to the equatorial plane extending to the stars. We know nothing, of course, of the reason for that angle of 62°, but it has its importance, because not only must the belt cross the equator at two opposite points, as it does in two opposite constellations, Aquila and Monoceros, but the poles of the Milky Way must lie at the points of greatest distance from the junction with the equator, in certain constellations. These are Coma Berenices and Sculptor, and the position of the N. galactic pole, as the pole of the Milky Way is called, is in R.A. 12h. 40m. Dec. + 28°. Now, although the Milky Way looks very unlike the other parts of the heavens, we have known since the time of Galileo that the difference arises from the fact that it is composed of a tremendous multitude of stars; and this is why I have drawn attention to it, a very large percentage of the masses of matter which compose our system lies in the plane of the Milky Way. It does not merely represent a fiery or igneous fluid, as different schools thought it did in the old days. So far as our opera-glasses and telescopes indicate to us, we are in presence of an innumerable multitude of stars. When, however, we come to look at it a little more closely, we find that from two points in it branches are thrown out, so that over some part of its orbit, so to speak, it is double; there is a distinct doubling of the Milky Way along a part of its length. But in spite of that, the middle line of the galaxy or the Milky Way is really not distinguishable from a great circle, as was formerly supposed. The great rift which separates these two parts of it begins near a star in the southern hemisphere, $\alpha$ Centauri, and it continues for more than six hours in right ascension until the two branches meet again in the constellation Cygnus, which is well within our ken in the northern heavens. The distance apart of the middle lines of these two components of the Milky Way where the split is most obvious is something like 17°, so that, in addition to the angle of 62° from the ecliptic, in some part of the Milky Way, there is another offshoot springing out of it at an angle of something like 17°. The regions of greater brilliancy correspond approximately to the places where the branches intersect each other. In short, there are sundry indications that the whole phenomena of the Milky Way may become simplified by treating it as the resultant of two superimposed galaxies. The general view till recently was that the Milky Way is not a great circle, because it was thought the sun was not situated in its plane. The whole mass of stars was likened to a millstone split along one edge, which was Sir William Herschel's first idea. But the recent work, chiefly of Gould in Argentina, has shown that it practically is a great circle. However that may be, in one part of the heavens this wonderful Milky Way appears as a single, very irregular stream, and in another part it appears to be duplicated.

It is impossible in this short course of lectures to attempt to give anything like an historical statement of the growth of our knowledge of the Milky Way. I can only refer you to the Milky Way itself; and the next time any of you have an opportunity of seeing it, just look at the wonderful majesty and complexity of it. We find in it indications of delicate markings going out into space, apparently coming back strengthened, of streams in all directions, of clusters clinging to those streams, and so on. In other parts it is curdled, which is the only term which I can use to express my meaning. In another part we may find it absolutely free from any important stars; in another we may find it mixed with obvious nebula; and in another we may find it mixed, not only with obvious nebula, but with a great number of bright-line stars involved, not only in the Milky Way, but in the nebula itself.

We have now, fortunately for science, priceless photographs of these different regions. One will give us an idea of the enormous number of stars in some parts; another one of the streams of nebulous matter which are seen in the Milky Way from region to region. Again we find a regular river of nebulous matter rushing among thousands of stars. In some the galaxy seems to tie itself in knots. There is an individuality in almost every part of it, which we can study on our photographic plates; practically there are no two parts alike. Others again bring before us the curdled appearance which is visible in different regions, and finally the connection of the infinite number of stars with obvious nebulous matter. In this way, then, we are enabled to form an idea of the general conditioning of things as we approach the Milky Way.

The next important point is that the enormous increase of stars in the Milky Way is not limited to the plane itself, but that there is really a gradual increase from the poles of the Milky Way, where we get the smallest number of stars. It is not very easy to bring together all the information, for the reason that different observers give different measures; they take different units for the space they have determined to be occupied by stars from the pole towards the galactic plane; and also the number of stars in the northern hemisphere is not the same as the number in the southern hemisphere. But roughly speaking we may say, if we represent the number of stars at the galactic pole by four, the number of stars in the galactic plane will be about fifty-four.

The following table will show the gradual increase in the number of stars from the pole to the plane, as seen by the Herschels with a reflecting telescope of eighteen inches aperture and twenty feet focal length :—[1]

| Galactic polar distance. | Average number of stars per field of 15′ | |
|---|---|---|
| | Northern. | Southern. |
| 0-15 | 4·32 | 6·05 |
| 15-30 | 5·42 | 6·62 |
| 30-45 | 8·21 | 9·08 |
| 45-60 | 13·61 | 13·49 |
| 60-75 | 24·09 | 26·29 |
| 75-90 | 53·43 | 59·06 |

A consideration of the distribution of stars in Right Ascension between declinations 15° N. and 15° S. led Struve to the conclusion that there are well marked maxima in R.A. 6h. 40m. and 18h. 40m., and minima in R.A. 1h. 30m. and 13h. 30m.; he remarks that the maxima fall exactly on the position of the Milky Way in the equator, and further states that "the appearance of the close assemblage of stars or condensation, is closely connected with the nature of the Milky Way, or that this condensation, and the appearance of the Milky Way, are identical phenomena."

Although the Milky Way dominates the distribution of stars, and especially of the fainter stars, it does not appear to be the only ring of stars with which we have to do. Sir John Herschel traced a zone of bright stars in the southern hemisphere, which he thought to be the projection of a subordinate shoot or stratum. That was the first glimpse of a new discovery, which was subsequently established by Dr. Gould in his work in the southern hemisphere at Cordova. He found that there was a stream of bright stars to be traced through the entire circuit of the heavens, forming a great circle as well de-

[1] *Outlines of Astronomy*, Herschel, pp. 535, 536.

fined as that of the galaxy itself, which it crossed at an angle of about 25°.

Gould, while in the southern hemisphere, had no difficulty in observing that along this circle, which we may call the Star-way, in opposition to the Milky Way, most of the brighter stars in the southern heavens lie.

When he subsequently came home he made it a point of study to see whether he could continue this line of bright stars among the northern hemisphere, and he found no difficulty. So that we may now say that the existence of this supplementary Star-way, indicated by the line of extremely bright stars, is beyond all question.

I quote the following from what Gould has written on this subject.[1]

"Few celestial phenomena are more palpable there than the existence of a stream or belt of bright stars, including *Canopus*, *Sirius*, and *Aldebaran*, together with the most brilliant ones in *Carina*, *Puppis*, *Columba*, *Canis Major*, *Orion*, &c., and skirting the Milky Way on its preceding side. When the opposite half of the galaxy came into view, it was almost equally manifest that the same is true there also, the bright stars likewise fringing it on the preceding side, and forming a stream which diverging from the Milky Way at the stars $\alpha$ and $\beta$ *Centauri*, comprises the constellation *Lupus*, and a great part of *Scorpio*, and extends onward through *Ophiuchus* towards *Lyra*. Thus a great circle or zone of bright stars seems to gird the sky intersecting with the Milky Way at the Southern Cross, and manifest at all seasons, although far more conspicuous upon the *Orion* side than on the other. Upon my return to the North, I sought immediately for the northern place of intersection; and although the phenomenon is by far less clearly perceptible in this hemisphere, I found no difficulty in recognising the node in the constellation *Cassiopeia*, which is diametrically opposite to *Crux*. Indeed it is easy to fix the right ascension of the northern node at about oh. 50m., and that of the southern one at 12h. 50m.; the declination in each case about 60°, so that these nodes are very close to the points at which the Milky Way approaches most nearly to the poles. The inclination of this stream to the Milky Way is about 25°, the Pleiades occupying a position midway between the nodes."

Gould also had no difficulty in showing that the group of the fixed stars to which I have just referred, at all events of fixed stars brighter than the fourth magnitude, is more symmetrical in relation to this new star line than to the Milky Way itself, and that the abundance of bright stars in any region of the sky is greater as the distance from this new star line becomes less. Practically five hundred of the brightest stars can be brought together into a cluster, independent of the Milky Way altogether—a cluster he points out of somewhat flattened and bifid form.

Not only do we find that the stars are very much larger in number near the Milky Way than elsewhere, but that the same thing happens with regard to the planetary nebulæ. Nebulæ generally, I am sorry to say, I cannot profess to discuss with any advantage, because there are very many bodies classed as nebulæ in the different catalogues about which we know absolutely nothing as to their physical nature. It will be remembered that many years ago the question of the real existence of nebulous matter in space was rendered very difficult by the fact that the larger telescopes, which were then being made by Lord Rosse, brought before us a great number of clusters, the stars of which were so close together that they seemed to form a nebulous patch, whereas on a finer night or with a better instrument we were able to see that we were simply dealing with distant clusters. I do not propose, therefore, to say anything about nebulæ generally, but to call attention to those points about which we can be most certain.

[1] *Amer. Jour. Sci.*, viii. p. 332.

We do know that, not only do we find stars increasing in number as the Milky Way is approached, but the undoubted star clusters also increase towards the Milky Way in a marvellous manner.

Bauschinger[1] (1889) in a review of Dr. Dreyer's New General Catalogue (7840 objects) discussed the distribution of different classes of objects and found that star clusters, by which he means of course resolved clusters, and planetary nebulæ congregate in and near the galaxy.

Mr. Sydney Waters some four years later, in 1893, brought together the nebulæ and the star clusters for us, and I propose to show the very important maps which he drew. He indicates a star cluster by a cross, and nebulæ by round dots. Practically the obvious star clusters are limited to the Milky Way. That is a very admirable way of bringing the knowledge with regard to any one of these distinct groups of stars before us, and it shows us in a most unmistakable manner that the star clusters, like the planetary nebulæ and stars generally, are very much more numerous in the plane of the Milky Way than they are in any other part of the heavens.

It is striking to note the fidelity with which the clusters follow, not only the main track of the Milky May, but also its convolutions and streams, while the remarkable avoidance of the galaxy by the nebulæ, excluding the planetary nebulæ, is obvious, indeed, it was remarked upon by Sir Wm. Herschel.

We have seen, then, that we have the greatest number of stars congregating in the plane of the Milky Way, the greatest number of planetary nebulæ and the greatest number of star clusters. We have next to consider whether any particular kind of a star congregates in the Milky Way or avoids it. In that way we shall be able to see the importance of this new chemical touch, which is now possible to us in our survey of the heavens.

The first attempt at such an inquiry as this was made in 1884 by Dunér,[2] who had made himself famous by his admirable observations on two different classes of stars —those which I have referred to as being defined by carbon flutings in one case and metallic flutings in the other. His work was practically the only research on the carbon stars—the stars, that is, with carbon flutings. He was, naturally, anxious to see how they were distributed, and he gives the number of these stars in varying parts of the heavens in relation to the Milky Way. He found that the numbers increased towards the Milky Way. The table I give will show the general result at which he arrived. We had, as we saw in the case of the ordinary stars, a very rapid progression in number from the pole of the Milky Way to the plane; we had three stars at the pole when we had fifty-three in the plane.

| Dist. from galactic pole. | Number. | Mean mag. |
|---|---|---|
| ° ° 0–35 | 3 | 6·6 |
| 35–60 | 8 | 6·6 |
| 60–70 | 8 | 7·2 |
| 70–80 | 13 | 7·4 |
| 80–90 | 29 | 8·3 |

Dunér found, with regard to his carbon stars, that there was distinctly an increase from the pole towards the plane, but we observe that the rate of increase was very much less in this case; so that, starting with three at the pole, he only found twenty-nine in the plane. Although then it was true that the number of stars did increase towards the Milky Way, they did not increase so rapidly as the stars taken as a whole; still, from his observations, we are justified in stating that

[1] *V.J.S. Ast. Ges.*, xxiv. p. 43.
[2] "Étoiles de la troisème Classe," p. 125.

there is an increase as we approach the plane of the Milky Way. They are, therefore, not limited to the plane. Now we know that these stars are the moribund stars, the stars just disappearing, the stars whose light is waning; so that soon after the carbon stage they exist in the heavens as dark stars, and we can only know their existence by their gravitational effect upon other stars which are self-luminous. It is also to be borne in mind that these stars, just because they are in their waning

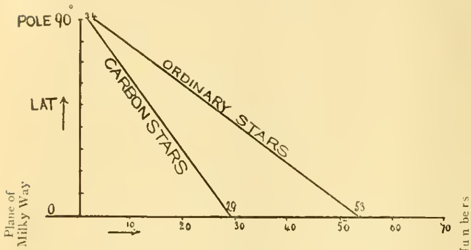

FIG. 2.—Comparison of relative numbers of stars generally and carbon stars.

stage, are very faint; so that the information we are able to get with regard to them may possibly be information concerning their distribution in parts of space not very far distant from that which we ourselves occupy.

That was in 1884. In 1891 Prof. Pickering, when he found that he had collected something like 10,000 stars in the Draper catalogue, began to consider their distribution in different parts of space in relation to the then classification, which was practically a classification founded on hieroglyphics, since we knew very little about the chemistry of the different bodies at that time.

He found that the Milky Way was due to an aggregation of white stars, by which he meant, as we now know, very hot stars, and the hottest of them, that is the gaseous ones, exist more obviously in the Milky Way than do the others. The proportional number of proto-metallic stars in the Milky Way was greater for the fainter stars than for the brighter ones of this kind, and that at once suggests a possibility that in the Milky Way itself there is a something which absorbs light; so that the apparently brightest stars are not actually the brightest, but are more luminous because they have not suffered this absorption, and that those which have suffered this absorption may be very much further away from us than the others of a similar chemistry. He also arrived at this extremely important conclusion, namely, that the metallic stars, that is, stars like our sun, stars more or less in their old age, had no preference for the Milky Way at all, but are equally distributed all over the sky. With regard to the group of stars known by metallic flutings in their spectra, he has no information to give us any more than Dunér had, for the reason that their number is small and they have not yet been completely studied.

Only last year this inquiry was carried a stage further by Mr. McClean, who not only photographed a considerable number of stellar spectra in the northern hemisphere, but subsequently went to the Cape of Good Hope in order to complete the story with reference to the stars down to the third or fourth magnitude, which he could observe there. He was very careful to discuss, in relation to the Milky Way and certain galactic zones, the distribution of the various kinds of stars which he was fortunate enough to photograph.

We notice that if we deal with the gaseous stars the numbers in the north and south polar region are small, and that the numbers nearer the Milky Way are greater, so that finally we can see exactly how these bodies are distributed. If we take the gaseous, that is to say the hottest, stars, we find the smallest number in the polar regions; but if we take the metallic stars we find practically the largest number, at all events a considerable number, in the polar regions. The general result, therefore, is that the gaseous stars are mostly confined to the galactic zones, the proto-metallic stars are not so confined, that is to say, down to about $3\frac{1}{2}$ magnitude. What is also shown there is that the metallic-fluting stars are practically equally distributed over the polar regions and over the plane of the Milky Way itself: so that, in that respect, we get for these stars very much the equivalent of the result arrived at by Dunér, that is to say, they have little preference for the Milky Way.

*(To be continued.)*

## *THE PARENT-ROCK OF THE SOUTH AFRICAN DIAMOND.*[1]

DIAMONDS were discovered in gravels of the Orange River in 1867, and were traced three years later to a peculiar earthy material called from its colour "yellow ground" by the miners. This, which was soon found to pass down into a more solid and dark-coloured material called "blue ground," occupies "pipes" in the country rock—carbonaceous shales and grits belonging to the Karoo system; the one standing in much the same relation to the other as do the volcanic necks to the carboniferous strata in Fifeshire. Flows or sills of basaltic rocks are associated with the sedimentary strata, and both are cut by dykes. The matrix of the blue ground is a fine granular mixture, chiefly consisting of a carbonate (calcite or dolomite) and serpentine. In this are embedded grains of garnet (mostly pyrope), pyroxenes (a chrome diopside, smaragdite or enstatite), a brown mica, magnetite and other ores of iron, and some other minerals more sparsely distributed. Rock fragments also occur; some of them are the ordinary shale and grit, but others are compact and of an uncertain aspect. Crystalline rocks are sometimes found.

As to the nature of this blue ground and the origin of the diamond, very diverse opinions have been expressed. The late Prof. Carvill Lewis considered the former to be a porphyritic peridotite, more or less serpentinised, which sometimes passed into a breccia or a tuff, and the diamond to have been formed *in situ* by the action of this very basic igneous rock upon the carbon present in the Karoo beds. Others, however, maintained that the rock was truly clastic; being produced by the explosive destruction of the sedimentary rocks, together with part of their crystalline floor—was, in fact, a kind of volcanic breccia, subsequently altered by the action of percolating water at a high temperature. But they also differed in opinion as to the genesis of the diamond itself; one party holding it to have been formed *in situ*, by the action of water at a high temperature and pressure, the other considering it, like the garnets, pyroxenes, &c., to have been formed in some deep-seated holocrystalline rock mass, and to have been set free, like them, by explosive action.

A few months ago the investigation had advanced thus far: (1) study of the diamonds obtained from the blue ground had increased the probability of their being derivative minerals; (2) no certain proof of the former existence of a compact or glassy peridotite had been discovered; (3) certain compact rock fragments, as to the origin of which the writer had at first hesitated to express an opinion, had been determined by him to be only argillites, affected first by the action of heat, then of water; (4) the diamond and the garnet had been brought into very close relation by the discovery of two specimens, showing the former apparently embedded in the latter. The better of them was accidentally picked up at a depth of about 300 feet in a shaft at the Newlands Mines, West

[1] The substance of a paper read before the Royal Society on June 1.

Griqualand (about forty-two miles to the north-west of the more famous group in the neighbourhood of Kimberley). In this specimen a rather large and irregularly shaped pyrope projects from one end of a fragment of blue ground: one small diamond is embedded in this pyrope, and five others either indent it or are in close contact. Fortunately the discoverer was the managing director of the company, Mr. G. Trubenbach, who appreciated its importance, and so kept a sharp look-out for anything remarkable which might turn up during the excavations. Accordingly he preserved specimens of certain boulders, sometimes over a foot in diameter, well rounded and just like stones from a torrent, which occasionally occurred in the blue ground at various depths down to 300 feet. Several of these contained garnets, being varieties of eclogite, but diabase was also obtained.[1] Some of these Mr. Trubenbach brought to London, and on the outer surface of one a small diamond was detected. The boulder was broken, and others were exposed. A fragment (rather less than a third) was sent to Sir W. Crookes, who entrusted it for examination to the writer, and to him Mr. Trubenbach afterwards sent other boulders, besides rock and mineral specimens, with the permission of the directors.

In addition to the boulder of diabase, which has no special interest beyond the fact of its occurrence, there are six boulders of eclogite (one perfect, the rest having been broken), all but one (which may have been four or five inches long) measuring a foot across, more or less. Three of these consist almost entirely of a garnet (pyrope) and an augite (chrome diopside), the former varying in size from a large pea downwards, and the other mineral corresponding. The pyrope is often surrounded, especially towards the exterior of the boulder, by a "kelyphite rim" consisting mainly of a brown mica. This and a few other minerals were present elsewhere, but in very small quantities. The remaining three boulders consisted of the same two constituents, with the addition of a considerable amount of a variety of bastite and a few flakes of brown mica. Of the first group of specimens two contain diamonds, the first-named having at least nine and another certainly one, perhaps a second. All are small, the largest being about ·15 inch in diameter. They are well-formed octahedra, with slightly stepped faces, perfectly colourless, with an excellent lustre. Evidently they are just as much an accidental constituent of the eclogite as a zircon might be of a granite or syenite.

This discovery leads to the following conclusions. As the diamond is found in boulders of eclogite, and these are truly water-worn, that rock is the birth-place, or at any rate one birth-place, of the diamond (for its occurrence in a more basic species, such as a peridotite, may be expected). Hence the diamond is not produced in the blue ground, but is present in it as a derivative from older rocks, in the same way as the olivine, the garnets, the various pyroxenes, &c. Moreover, the blue ground is a true clastic rock, and not a serpentinised peridotite of any kind, so that the name Kimberlite, proposed for it by Prof. Lewis, must disappear from that group. The rock is a volcanic breccia, though a rather peculiar one, for scoria has not yet been detected in it. Probably it was formed by explosions due to pent-up steam, the vents being driven through the upper part of the crystalline floor and the overlying sedimentaries. These never ejected lava, and were soon choked up with shattered material. Through this, in all probability, steam or heated water continued to be discharged for a considerable time, which accounts for the marked changes effected in the exterior of the larger fragments and in the more finely pulverised material of the matrix.

T. G. BONNEY.

[1] The occurrence of boulders in the blue ground at De Beers Mine was asserted by Stelzner in 1893 (*Sitzungber. u. Abhandl. der Isis*, 1893, p. 71).

## NOTES.

WE are informed that copies in bronze of the medal presented to Sir G. G. Stokes at his jubilee can now be obtained from Messrs. Macmillan and Bowes, Cambridge, price 15*s*. each.

AT the opening meeting of the new session of the Institution of Civil Engineers, on November 7, an address will be given by the president, Sir Douglas Fox, and the prizes and medals awarded by the Council will be presented.

A GOLD medal is offered by the Cercle industriel agricole et commercial, Milan, for the description of a method, or the construction of apparatus, which will assist in the prevention of accidents to artizans engaged in electrical work.

A CONVERSAZIONE of the Geologists' Association will be held in the library of University College on Friday, November 3. A number of pictures and objects of geological interest will be on view during the evening.

THE Allahabad *Pioneer Mail* (October 6) states that Mr. Douglas Freshfield has started from Darjeeling, with a party of friends and Alpine guides, to explore the glaciers and little-known passes of the Kanchenjunga range. The exact course to be pursued is probably unknown to the party themselves, who must be guided by circumstances; but any addition to the scanty and inaccurate information at present extant on the subject of the Himalayan giant will be welcome to geographers.

IT is stated that another British exploring expedition to Abyssinia has been arranged, and will leave England at once. The members are Mr. James J. Harrison, Mr. Powell Cotton, Mr. W. Fitzhugh Whitehouse (of Newport, Rhode Island) and Mr. A. E. Butter. Mr. Donald Clarke will go as surveyor and geographer, and a taxidermist will also accompany the party. The objects of the expedition are scientific and sporting, and it is expected that the journey will occupy about nine months.

THE thirty-eighth annual general meeting of the Yorkshire Naturalists' Union is to be held at Harrogate to-day, and an address upon the evolution of plants will be given by Mr. William West, the retiring president. The Union is a model of a well-organised local society, which not only serves to develop interest in science, but also assists in the extension of natural knowledge. The membership is not in any way commensurate with the importance of the work carried on, and we are glad to see that efforts are to be made during the forthcoming winter to bring the claims of the Union for support before the naturalists and the public of the County of York.

THE *British Central Africa Gazette*, published at Zomba, always contains several items of scientific interest, and the latest number received, dated August 24, is not deficient in this respect. We learn from this source that Mr. J. E. S. Moore has been taking soundings at the north end of Lake Nyasa. Off Ruarwe a depth of 418 fathoms was found, and off the higher parts of Livingstone Range bottom was reached at 210 fathoms.—Mr. Poulett Weatherley describes in a letter a difficult journey up the Luapula, and through its innumerable rapids. The Luela is regarded as the second most important tributary of the Luapula, but there is little to choose between the Luombwa, the Luela, the Mwyangashe and the Luongo, though the Luombwa is the largest and most delightful of the four.

REUTER'S correspondent with Major Gibbons' trans-African expedition reports from Lialui (Barotsiland), in a despatch dated August 5, that much valuable exploring work had been done by the members of the expedition. The routes traversed by the travellers since last January amount in the aggregate to 3500 miles, mostly through unknown or unexplored districts.

The plans of the party at the date of the despatch are reported to have been as follows:—At the end of this month Captains Quicke and Hamilton will travel east to the Kafukwe, while Major Gibbons will make a journey up the Zambesi with canoes to Nanakandundu, returning by river as far as the Kabompo confluence, whence he will make a line to the Kafukwe. Captain Hamilton will then travel down that river to its confluence with the Zambesi, where an aluminium boat awaits him, in which he will descend the river to Zumbo, and return home *via* the east coast. Major Gibbons with Captain Quicke will travel up the Kafukwe, and, after following the Zambesi from its source to Nanakandundu, will make for St. Paul de Loanda on the west coast. All three hope to reach the coast in December by their respective routes.

THE long-standing question as to the admittance of women into full fellowship of scientific societies was brought before a meeting of the Lady Warwick Agricultural Association for Women on Thursday last, and the following resolution, supported by a paper by Mrs. Farquharson, was adopted: "That it is desirable and important that duly qualified women should have the advantages of full fellowship in scientific and other learned societies, *e.g.* the Royal, the Linnean and the Royal Microscopical." The arguments in favour of and in opposition to this proposal have been stated so many times that most members of scientific societies are familiar with them. Six years ago the Council of the Royal Geographical Society elected several ladies as fellows, but their action was disapproved at two special meetings, and resolutions to the effect that it was inexpedient to admit ladies as ordinary fellows were carried by conclusive votes. Ladies are, however, admitted to the meetings of the Society, and papers are accepted from them. In the case of the Royal Astronomical Society, ladies are only admitted to the ordinary evening meetings by special invitation of the president, sanctioned by the Council, the invitations being issued at the commencement of each session. The time may of course come when women will be equally eligible with men for membership of the learned societies, but facts such as those cited show that there is distinct opposition to the admittance of women at present, and no sudden change of feeling can be expected, though individual cases of "duly qualified" women might be considered.

IN a review which appeared in NATURE of September 7 (p. 433), reference was made to the hair of a "Panyan woman," figured as a "Negrito type, India," in Prof. A. H. Keane's work on "Man, Past and Present." Mr. Thurston's original photograph, from which the illustration was reproduced, shows the hair of the woman as of a distinctly curly character, "which feature," the writer of the review remarked, "is unfortunately lost in Keane's reproduction." Prof. Keane writes to say that his picture is a facsimile of Mr. Thurston's photograph, and shows the curly hair portrayed in the original. In support of his case he has submitted the portrait and the reproduction to us, and we must confess our inability to distinguish any obvious difference between them. The writer of the notice maintains, however, that the hair is not quite the same in the two, and he unites with Prof. Keane in the hope that every one interested in the matter will compare the illustrations for themselves before accepting either view.

DR. C. LE NEVE FOSTER reports, in a Blue Book just issued ("Mines and Quarries: General Report and Statistics for 1898," part iii.), that the total value of all minerals raised in the United Kingdom in 1898 exceeded 77,000,000*l.*, being an increase of five millions compared with the previous year. The output of coal during the year exceeded 202 million tons, of which 36½ million tons were exported. This large export of coal induces Dr. Foster to call attention to the plain warning contained in Mr. T. Forster Brown's paper on "Our Coal Supplies" (*Journal* Society of Arts, 1899, p. 508), in which it is emphatically stated that in another fifty years the dearth of cheap coal will begin to be felt. Referring to this, Dr. Foster says: "We are already dependent upon foreign countries for much of our iron ore, and it will be an evil day when we feel the pinch of poverty in coal. The proper husbanding of the coal resources of the kingdom is therefore a question of national importance."

THE great success of the installations for the development of electricity by power obtained from Niagara Falls is naturally leading enterprising capitalists in many other parts of the world to consider similar projects. We learn, for instance, from the *Pioneer Mail* that within the last few months schemes have been ventilated for utilising the Nerbudda at the Marble Rocks for supplying power to the new gun-carriage factory to be erected near Jubbulpore. There is also a project for running the Kashmir railway by electricity, the power being taken from the Chenab. Then there is another plan for supplying electrical power to Murree, deriving the energy from the Jhelum, which runs within ten or twelve miles of that sanatorium. For Simla there are no less than two schemes for obtaining electrical power by hydraulic means: one from the Sutlej, and another from a proposed lake to be made in the nullah below the station. Assuming that the majority of these schemes are practical, the point which remains somewhat obscure for the present is whether the demand for electricity in any of the places named would be sufficiently great to make the undertaking a commercial success.

THE *Experiment Station Record* (No. 5) of the U.S. Department of Agriculture contains a description of the biological and dairy building recently completed by the New York State experiment station at Geneva. The building has been constructed and equipped by the State for the study of dairy problems, and especially those concerned with cheese-making. The changes which take place during the curing of cheese, and the conditions which influence them, are still so imperfectly understood that the work carried on in the new laboratories is sure to lead to valuable results. Arrangements are provided for studying the ripening process in all its phases; and a bacteriologist is attached to the staff.

A NUMBER of excellent photographs obtained with a telephoto lens, by Mr. D. L. Elmendorf, are reproduced in the current number of *Scribner's Magazine*. A telephoto attachment, consisting of a negative lens, with a rack and pinion mounting, was used upon an ordinary rectilinear lens to take the pictures. With this attachment eight inches from the plate, the image obtained was equal to that formed by an ordinary lens of twenty-four inches focus; while at twenty-four inches from the plate, this being the greatest extension of the camera employed, the combination was equivalent to a lens of sixty-four inches focus. Among the striking pictures which accompany Mr. Elmendorf's article are views of the Jungfrau, obtained at a distance of sixteen miles, and of the cone of Popocatepetl, Mexico, taken at a distance of thirty miles.

THE Pilot Chart of the North Atlantic Ocean for the current month contains some further interesting particulars respecting the track of the destructive West India hurricane of August 3–September 12. After leaving the American coast it at first moved eastward with increased velocity. During the week of August 24–30 it remained almost stationary in the mid-Atlantic, the centre of the disturbance shifting to the northward, from where it took an almost due easterly course to about longitude 20°, traversing the Azores on September 3; it then curved to the N.E. until it reached the vicinity of Brest on September 7, when it bent in a S.E. direction and reached the north of

Corsica on September 9. Whole gales were frequently encountered throughout the course of the storm across the Atlantic. Off the coast of Provence it caused strong N.W. gales and a rough sea on September 9–11. This hurricane can be traced over the North Atlantic for a period of thirty-six days, making it in length of life the most noteworthy storm ever reported to the Hydrographic Office in Washington.

A summary of divers and sundry views respecting the cause of formation of hail is given by Signor Pio Bettoni in the *Bolletino mensuale* of the Italian Meteorological Society. The great divergence of opinion on the subject seems to suggest that we have not made much advance towards arriving at a definite explanation of the phenomenon during the century which has elapsed since Volta published his well-known electrostatic theory. Of the views here enumerated some are modifications of Volta's theory, and attribute the formation of hail to electrostatic causes, others ascribe the phenomenon to whirlwinds (vortices), others, again, to refrigerating air currents, and even the more unconventional theories, according to which hailstones come to the earth from interplanetary space or their refrigeration is due to transmutation of caloric into electricity, are not without their advocates.

In *Himmel und Erde* for September, Dr. E. Less, of the Berlin Meteorological Office, gives a very lucid account of the general circulation of the atmosphere. In the first half of this century our knowledge of weather changes was almost exclusively confined to climatological investigations, in which Prof. Dove, of Berlin, was the most prominent representative; he referred the origin of all winds to an interchange of the air between the equator and the poles. But the study of synoptic weather charts, from about the year 1860, showed that the explanation hitherto given of weather changes did not generally accord with observed facts, and that they were intimately connected with the existence of areas of high or low barometrical conditions. The author points out that while the behaviour of the great atmospherical currents is, generally speaking, capable of explanation, the relation between them and the smaller disturbances which occur in our latitudes leave many doubtful points to be cleared up. In fact, what part is played by the general and what by the local conditions in producing the different phases of weather is as yet but little understood. The explanation of these phenomena is one of the most important problems of meteorological research, the solution of which must be approached in various ways.

The *Bulletin International* of the Cracow Academy contains a notice of a paper, by M. P. Rudski, on the theory of the physics of the earth. In it the author gives a mathematical investigation of the variation of latitude in an elastic spheroid covered with water, and investigates the earth's rigidity as deduced from the 430-day period of the variation. The values deduced depend on the assumed "effective density" of the earth. Taking for this density the values 2·2, 3·0, 4·0, 4·5 and 5·5, Rudski finds the corresponding values of the rigidity to be 567, 879, 1713, 2036 and 2681 times $10^9$ C.G.S. units respectively, that of steel being $819 \times 10^9$. By neglecting the effects of the ocean, and taking for the effective density the value 5·5, the author finds $n = 1250 \times 10^9$.

With a view of contributing data towards the determination of the secular variations of the earth's magnetism, Dr. Emilio Oddone contributes to the *Rendiconti del R. Istituto Lombardo*, xxxii. 15, his determinations of the magnetic elements at Pavia for June 1898, which admit of comparison with the corresponding elements determined by him at the same spot about fifteen years ago. The present results are as follows: declination, 11° 48′ ± 2′; inclination, 61° 26′ ± 2′; intensity in C.G.S. units, horizontal, $0{\cdot}216_3 \pm 0{\cdot}001$; vertical, $0{\cdot}397_3$; total, $0{\cdot}452_4$. While the interval between the present and the previous determination is too short to allow of these observations being made the basis of a new determination of the secular variations of the earth's magnetism, the author remarks that the empiric formulæ for the inclination and horizontal intensity, when exterpolated for fifteen years, agree fairly well with the above-mentioned numbers, but the annual variation in late years comes out to be less than was to be inferred from past observations.

Profs. Elster and Geitel, writing in *Wiedemann's Annalen*, 69, discuss the source of energy in Becquerel rays, and advance the theory that the rays may be due to changes of the molecular arrangement of the atoms of the radio-active substance in which these pass from an unstable to a stable configuration with expenditure of energy. In a second note, the same authors show that Becquerel rays experience no deviation from a magnetic field, but that such a field in certain circumstances decreases the electro-dispersive power of air that has been traversed by them.

In a communication to *Wiedemann's Annalen*, 67, Herr K. Kahle describes at some length experiments with the silver voltameter and their applications to determine the electromotive force of normal elements. The object of the paper is to obtain the electromotive force of the Clark cell, previously determined by the author by means of Helmholtz's electro-dynamometer, independently from the electro-chemical equivalent of silver. The value now obtained for the ratio of the Clark at 15° to the cadmium at 20° is 1·40663. Herr Kahle infers the following results as correct to 2 in 10,000, viz. Clark, 15°: $1{\cdot}4328_5$; cadmium, 20°: $1{\cdot}0186_3$; and Clark, 0°: 1·4492 internal volts.

Dr. Franz Kerntler has published a paper on the unity of the absolute system of units in relation to electric and magnetic measurements, in which he proposes to supersede the present dual systems of electrostatic and electromagnetic units. According to Dr. Kerntler's system, quantity of electricity and quantity of magnetism are both measured by Coulomb's law in C.G.S. units, and are thus both of the same dimensions, being identical with the electrostatic and magnetic units respectively; but a current has two measures, which Dr. Kerntler designates as its "opulence" and its "fecundity." These, which represent its electromagnetic and electrostatic measurements in common parlance, are in the ratio of 1 to "$v$."

Dr. F. J. Allen has contributed to the *Proceedings* of the Birmingham Natural History and Philosophical Society, xi. 1, an essay on the nature and origin of life. The author remarks that the most prominent and perhaps most fundamental phenomenon of life is what may be described as the energy traffic or the function of trading in energy. After briefly pointing out the differences between anabolism and catabolism, Dr. Allen advances the opinion that it is nitrogen which, in virtue of its variability, instability, and lability, plays the most important part in the phenomena of life, and he enunciates the law that every vital action involves the passage of oxygen either to or from nitrogen. In the section dealing with the origin of life, it is stated that life in its physical aspect is the culmination of that chemical instability in certain elements which has always kept them circulating at the earth's surface. Dr. Allen considers that existing conditions are favourable to the origination of primitive forms of vital processes at the present time, and the reason that such forms do not originate now is that the elements required for their development are seized and assimilated by the already developed organisms. In regard to the possible existence of life in other parts of the universe, the same conditions of instability which are peculiar to the group of elements

nitrogen, oxygen, carbon, and hydrogen at ordinary temperatures on our earth's surface may exist in other groups of elements at widely different temperatures, giving rise in parts of the universe, even of the most diverse characters, to developments of life whose variety and magnificence are beyond the utmost reach of our imagination.

A PAPER, entitled "Wanted, Plant Doctors," is to be found in the current issue of the *Contemporary Review*, in which the importance of the subject of plant pathology is briefly dealt with. While giving credit to the workers at the British Museum, Kew, &c., for the attention they are paying to this branch of science, the writer of the paper shows how far behind America and Germany this country is in recognising the importance of the subject. He thinks, however, that this will not be always so; "a time must come when every agricultural district will have its plant doctor, and when specialists in animal parasites, cryptogamic botany, and bacteriology will be consulted in difficult and obscure cases, just as the help of Harley Street is called in by medical practitioners. The practice of plant medicine is in its infancy; but with increased competition in the growth of cultivated crops, the farmer cannot afford to neglect any help that he can get in keeping the plants under his care in as high a state of health as possible." "What better use," adds the writer, "can be found for a philanthropist's money than the founding of a school of practical plant pathology, for the investigation of the diseases which occur in Britain?"

IN the October number of the *Zoologist* the editor, Mr. W. L. Distant, continues his communication on mimicry. While referring only to a limited number of examples, he divides his subject primarily into demonstrated, suggested and disputed cases of mimicry; adding a section on purposeless mimicry, and a second devoted to active mimicry. Under the heading of suggested mimicry the curious resemblances between certain tree-shrews and squirrels, as well as that between the Cape hunting-dog and the spotted hyæna, are rightly included; but it seems a little curious to find the East African Guereza monkey, whose coat has been shown by Dr. J. W. Gregory to present such a remarkable resemblance to the pendent lichens of the trees on which the animal lives, included in the same category. Under the heading of purposeless mimicry are included cases like the resemblance of the bee-orchis to the insect from which it takes its name; while active mimicry denotes those instances where insects or other creatures take special measures to avail themselves of their resemblance to other objects.

THE same journal likewise contains a very suggestive paper by Mr. C. Oldham on the mode in which bats secure their insect prey. It has been observed that these animals, when walking, carry the tail curved downwards and forwards, so that the membrane connecting this organ with the hind legs forms a kind of pouch or bag. If a large insect be encountered the bat seizes it with a snatch, and slightly spreading its folded wings and pressing them on the ground in order to steady itself, brings its feet forwards so as to increase the capacity of the tail-pouch, into which, by bending its neck and thrusting its head beneath the body, it pushes the insect. Although the latter, especially if large, will often struggle violently, when once in the pouch from which it is subsequently extracted and devoured t but rarely escapes. It is assumed that the sme method of capture is employed when on the wing; and a correspondent of the author, who has observed the long-eared bat picking moths off sallows, states that "the bat always hovers when taking off the moth, and bends up the tail so as to form a receptacle for the insect as it drops."

MR. G. C. WHIPPLE and Mr. D. D. Jackson reprint, from the *Journal* of the New England Water-works Association, a paper on *Asterionella formosa*, a diatom which sometimes appears in great quantities in reservoirs of drinking water, imparting to it a geranium-like or fishy odour, from the production of a substance analogous to the essential oils. Its development is seasonal, appearing chiefly in spring and autumn. Its growth is greatly favoured by strong light; and the most efficacious preventative appears to be the storage of the water in the dark.

THE Director of the Botanical Garden at Buitenzorg, Java, has issued the first number of a *Bulletin* of the Botanical Institute, containing a history of the Institute down to the present time, a plan of the buildings and of the gardens, with a list of the plants grown in them, and a list of the official publications. Besides the special laboratory for workers from other countries, the Institute contains laboratories for agricultural chemistry, for phyto-pathology, for agricultural zoology, for pharmacology, and for the study of the coffee and tobacco plants.

PROF. DAVID G. FAIRCHILD gives, in the *Botanical Gazette* for September, an interesting account of a visit to Payta, in Peru, reputed to be the driest spot on the face of the globe. Payta is situated about 5° S. of the equator on a coast which has risen 40 feet within historic times. The average interval between two showers is seven years; when Mr. Barbour Lathrop and Prof. Fairchild visited it in February, there had recently been rain lasting from 10 p.m. one day till noon the next day, the first for eight years. There are frequent sea-fogs. The flora consists of about nine species; of these seven are annuals, the seeds of which must have remained dormant in the ground for eight years. Notwithstanding the scarcity of rain, the natives subsist by the growth of the long-rooted Peruvian cotton, which is able to maintain itself without rain for seven years in the dried-up river-bed, and yields profitable crops of the coloured short staple cotton, which is used as an adulterant for wool.

THE Calendar, for the session 1899-1900, of the University College of North Wales has just been issued by J. E. Cornish, Manchester; and the University Correspondence College Press has published its London University Guide for the same period.

THE *Bulletin of Miscellaneous Information* (Botanical Department) for Trinidad, No. 20, July 1899) contains a report, by Mr. G. Massee, on the cacao pod disease, in which he states that, in addition to the well-known *Phytophthora omnivora*, a second parasitic fungus, *Nectria Bainii*, sp. n., occurs on the diseased pods.

WE have received from the Purdue University Agricultural Experiment Station at Lafayette, Indiana, a parcel of reports (*Bulletins* Nos. 71-79) on various subjects o' practical importance to agriculturists:—The San José and other scale insects; field experiments with wheat; skim milk as food for young growing chicken, &c.

PROF. ELMER GATES describes in the *Scientific American* a number of pictures he has obtained of the electric discharge, by placing a photographic plate between the two poles of a ten-plate electrostatic machine. The illustrations accompanying the article are of much the same character as those given by Lord Armstrong in his elaborate work on "Electric Movement in Air and Water," but they are on a smaller scale, and therefore less full of detail.

A NEW edition—the fourth—of "Our Secret Friends and Foes," by Prof Percy Frankland, F.R.S., has been published by the S.P.C.K. The author has re-written the chapter which was added to the immediately preceding edition, and has added some of the latest results achieved in the study of bacterial

poisons, such as that of bubonic plague, and of some other poisons of a non-bacterial origin.

MESSRS. LONGMANS AND CO. have issued a new edition of Prof. Lloyd Morgan's "Animal Biology." The book was originally published twelve years ago to meet the requirements of the Intermediate Science and Preliminary Scientific Examinations of the London University. The present edition has been revised, and some chapters re-written, to meet the requirements of the existing syllabus. Several illustrations now appear in the work for the first time.

NEW editions of two well-known books of chemistry (Ostwald's "Grundriss der Allgemeinen Chemie," and Lothar Meyer's "Outlines of Theoretical Chemistry," the latter translated by Profs. Bedson and Williams) have recently come to us from their publishers—Engelmann of Leipzig, and Longmans and Co The former is a third edition, and the latter a second, and an attempt has been made in each case to bring the work up to date.

REFERENCES to practically every article and work on geography published during the year 1896 will be found in the fifth volume of the "Bibliotheca Geographica," prepared by Dr. Otto Baschin for the Berlin Geographical Society, and just published by the firm of W. H. Kühl. A comprehensive classification of subjects is adopted, and it is easy to find the works published in any branch of geography in 1896. In adtion, there is a complete index of authors. Students of geography know the work so well that no comment upon its thoroughness is necessary here.

THE additions to the Zoological Society's Gardens during the past week include a Green Monkey (*Cercopithecus callitrichus*) from West Africa, presented by Mr. G. P. Kinahan; a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mr. A. M Burgess; a Gambian Pouched Rat (*Cricetomys gambianus*), a Nilotic Trionyx (*Trionyx truinguis*) from Sierra Leone, presented by Mr. Ernest E. Austen; a Red-footed Ground Squirrel (*Xerus erythropus*) from West Africa, presented by Mr. F. H. D. Negus; two Herring Gulls (*Larus argentatus*), British, presented by Mr. J. W. Edgar; a Melodious Jay Thrush (*Leucodioptron canorum*) from China, presented by Mrs. Currey; a Spoonbill (*Platalea leucorodia*), a Kestrel (*Tinnunculus alaudarius*), captured at sea, presented by Captain E. W. Burnett; a Green Turtle (*Chelone viridis*) from Ascension, presented by Mr. W. Hebden, C.E.; a Chameleon (*Chamaeleon vulgaris*) from North Africa, presented by Mr. F. G. Ward; two Serrated Terrapins (*Chrysemys scripta*) from North America, a Bennett's Cassowary (*Casuarius bennetti*) from New Britain, a White Goshawk (*Astur novae-hollandiae*), two Sacred Kingfishers (*Halcyon sancta*) from Australia, a Forsten's Lorikeet (*Trichoglossus forsteni*) from the Island of Sambawa, a Ring Ouzel (*Turdus torquatus*), British, deposited; a Crabeating Raccoon (*Procyon cancrivorus*), two Short-eared Owls (*Asio brachyotus*) from South America, purchased.

NOVA SAGITTARII.—*Harvard College Observatory Circular*, No. 46, gives the details of the position of Nova Sagittarii, discovered in April 1898, as obtained from micrometric measurement of enlargements from the plates, taken with the 8-inch Bache and 11-inch Draper telescopes, on which the star was photographed. Prof. Pickering finds that the accuracy obtainable by this method is equal to that given by the best meridian circle observations. The mean position as determined is

$$\left.\begin{array}{l}\text{R.A.} = 18\text{h. } 56\text{m. } 12{\cdot}83\text{s.}\\ \text{Decl.} = -\ 13^{\circ}\ 18'\ 12''{\cdot}98\end{array}\right\}(1900).$$

ORBIT OF EROS.—In the *Astronomische Nachrichten* (Bd. 150, No. 3597), Herr Hans Osten, of Bremen, discusses the numerous observations of the new minor planet now available, and gives the two following provisional sets of elements for the orbit:—

*Epoch of Nodal Passage*, 1898 *Oct.* 1·0. *Berlin Mean Time.*

STRASSBURG OBSERVATORY.—The annual publication compiled under the supervision of Herr E. Becker, the director of the Imperial Observatory of the University of Strassburg, has recently been issued, containing the reductions of star observations made during the period 1882–1888, together with miscellaneous results to 1893. The observations made with the meridian circle, occupying 154 pages, are preceded by some twenty pages giving details of the determination of collimation, level, azimuth and other corrections. Following these are given the individual observations of the positions of 223 stars measured from 1882–1883, and of 1146 stars measured during the period 1884–1888. From these three catalogues are compiled, one of 254, one of 858, and one of 368 stars, the latter containing corrections from Epoch 1880. Three appendices deal with heliometer measures of the partial solar eclipses of 1890, 1891 and 1893, the determination of the form the pivots of the meridian circle of the observatory, and the compilation of precession tables (both annual and secular) respectively.

## THE NERVE-WAVE (LA VIBRATION NERVEUSE).[1]

AS you told us, sir, two days ago in your admirable address, the century now drawing to an end is most honoured in the close union of men of science of all nations. If, owing to stupid prejudices and barbaric hate, nations are still separated by divisions which may lead them into fratricidal war, it falls to the men of science at least to set the example of concord, in order that by their teaching, based on reason, they may bring to all peace, sweet peace—the chimæra of the past, the hope of us all to-day, the reality of to-morrow. To this end nothing can be more effective than the great example of the British Association and the Association Française, who, within the space of a few days, are to meet twice as partners in their fertile work: to-morrow on English soil, in this hospitable town of Dover; five days later on the soil of France, on the shores you can see from here, where you will find the same courteous and cordial welcome as our countrymen will receive on this side.

Yet after these words of peace must come words of war—nay, its open declaration. Men of science have not the right to stay within the closed gates of their tower of ivory; it behoves them also, even at the cost of vain popularity, to wrestle and to wrestle unceasingly for justice; to form a grand international league, to turn the united forces of all generous minds against the common foe, the worst enemy of man: and this is ignorance. We must not value unduly the admirable conquests won by science in this century. Admirable as they are, they are yet nothing as compared to the great mystery beyond. Newton compared our science to that of a child, who should pick up a pebble on the

[1] Evening Address delivered by Prof. Charles Richet on September 15, at the Dover Meeting of the British Association. Translated by Prof. Marcus Hartog.

sea shore, and think he has penetrated the secrets of ocean. After all our searchings and all our efforts, to-day we can hardly say more. The shades that surround us are as deep as in the time of Newton; and in this universe, vast and obscure, at most scattered glimmers of light, few and far between, reach our straining eyes.

We need all the co-operation of all men of science, of all nations, to dispel some of these shades. What madness it would be not to unite, not to walk hand in hand, but to strive apart! The reward of this union will be above all price: the conquest of truth, the control of brute matter, the gift of a life less precarious and less painful to man, feeble man.

And so you see what we should think of those self-styled patriots and nationalists, who speak of French science, English science, German science, as if science were not international, and lifted high above our vain frontier limits.

To the history of nerve-waves many workers of diverse countries have contributed their share; as with every great scientific problem, every country of the world has taken part in its solution. But before I go on, let me pray your indulgence for treating of so arid and so difficult a subject before you.

I.

The world around us presents itself in different aspects to the eyes of the student and of the layman. The layman sees external objects, endowed with properties apparently inherent in them, and commonly defined by the impressions made on our senses. A given object is warm, light, electrified, heavy, and so forth; and every one thinks that heat, light, electricity, weight, are so many realities, distinct from the object itself. But the man of science conceives matters otherwise. For him this vast universe is formed of an indefinite "something" termed "Energy," and he knows that this force may have different manifestations in motions of diverse kinds. We are almost justified in saying that "Energy is one"; that its aspects appear to our senses so different because the various movements of this energy have not all the same qualities. They differ in number, in frequency, in rapidity, in form; and according to these different modalities which we perceive, and to their results, we have heat, light, electricity, attraction.

The movements of this energy are all transmitted in the same way, by wave-motion—"undulation" or "vibration," as we call it; and the physicists, by wonderful research, in which the highest mathematics must be utilised, have succeeded in determining the forms of certain kinds of these waves. And even those motions of energy which we do not so well understand, we are justified, by what we do know, in regarding also as wave-motions or undulations.

I need not dwell on this phenomenon of undulation or vibration. We all know the simple case when a pebble is dropped into still water: and the surface, which was smooth as a mirror, now shows a series of disturbances propagated in ever-widening concentric circles. In each oscillation we see two periods: in the one the water recedes from the primitive plane of the mirror, in the other it comes back to it again. The former is the *period* of *departure*, the latter that of *return*.

So, if we hit a hanging weight, a pendulum, the shock at once removes it from its position of equilibrium, and it recedes further from it (period of departure); then it comes back again to its starting point (period of return). What I have called undulation and vibration are two names for the same phenomenon, of the greatest diversity in form, but essentually due to the wave-motion of a fluid. Though, if you will, this fluid, the ether, be of very hypothetical character, we will take it for granted here, and say that heat, light, electricity, gravitation, are all wave-motions of the ether.

Consequently, the outer world in its infinite diversity of aspect, in form and in colour, is the sum total of the various vibrations of force. These vibrations, most diverse in character and in intensity, act upon the living organism, and produce sensations therein. Now it is probable that, as I shall try to show you directly, these vibrations of the outer world only act on our senses by evoking within us another kind of vibration, to which are due sensation and perception. Thus the nerve-wave is revealed to us as the goal and the final term of the vibrations of the external world. Were there no nerve-wave, though, no doubt, all these external vibrations would still exist, still they could produce no effect on us. In virtue of its own proper vibrations, the living being becomes the microcosm, the recipient of the diverse vibrations of the macrocosm, the universe: by these vibrations only is the universe accessible to our understanding. Thus you see what of interest lies in the study of this nervous vibration, since through it the outer world is known to us, and through it we have the power to act on the outer world.

II.

This study is no new one; I should trespass beyond the limits of your courteous attention were I to try and recount all the classical facts that are well known at present. Yet, that you may understand the new facts I am coming to presently, I shall have to give you a short summary of some of these classical facts; and I hope that despite their being so well known, they will not be devoid of interest to you.

The nervous system is made up of distinct elements, each consisting of a cell, with very long fibrous outgrowths. These cells with part of their outgrowths are compacted into the central nervous system, while the rest of the outgrowths are produced into strands, the peripheral nerves. An elaborate microscopical analysis of the last few years, largely due to Golgi and to Ramon y Cajal, have shown that the total number of processes is countless. Each cell sends forth at least one outgrowth, the *axis cylinder*, which remains unbranched except at its very termination; while the others, like the branching roots of a forest tree, spread out in all directions, so that they interlace with those of its neighbours. Thus all the nerve-cells are in communication; the disturbance of one may affect all. And this disturbance may be propagated far and wide; for in the peripheral nerves pass out the axis-cylinders, which separate ultimately and get up to the very tips of the limbs, to the skin, the entrails, the muscles, and the glands. Think of the whole surface of the skin as provided with little nerve apparatuses, all capable of vibration and of transmitting their undulations through the sensory nerve-fibres to the nerve-centres; of the nerve-centres as possessing processes like the sensory fibres, whereby to transmit their orders to the muscular and glandular organs; and you will be able to realise the part played by the nerves in the life of the organism. It is a vast telegraphic apparatus, to receive, by its sensory receptive mechanism, all impressions from without, and to transmit, by its transmitting mechanism, corresponding messages to the organs of motion, the muscles. And, since all the nerve-cells are, moreover, in communication with one another, and since every living cell is in relation with nerves, we may sum up the relations of the living organism in this general formula: through the nervous system, any one living cell reverberates in every other cell, and is reverberated to by every other cell. Thus the living organism that possesses a nervous system is no mere aggregate of cells; it is an *individual*, all the parts of which co-operate for the common weal.

The nerve-cell, together with its prolongations, has received the name of "neuron"; we can conceive that by the interrelations of all its neurons the living organism may be regarded as one gigantic neuron, sensible to all stimulations at the periphery, and answering them by stimulations of the motor apparatus, which are translated into acts of motion or of secretion. This sensibility and its motor response are linked by a phenomenon which we shall call for the present the "nerve-vibration" or "nerve-wave." How far is this name justified? This is the question that we have to deal with.

III.

Let us for the moment make the assumption (which is not quite exact) that the phenomena are identical in the peripheral nerves and in the central nervous centre, and that what applies to the one will also apply to the other.

We may, at least, accept them as analogous, since the axis-cylinder of the peripheral nerve is an expansion of the protoplasm of the nerve-cell. True, the reactions of the peripheral and of the central nerve tissue are not identical; but their differences are probably in accessories, not in essentials. We may, therefore, boldly accept their analogy, if not their identity; and we are justified in applying to the one the truth that we learn of the other.

The pace at which an impulse travels along a nerve is well known since 1850. Strange to say, just two years before, a great physiologist, one to whom the science is indebted for some of its grandest advances, Johannes Muller, declared that it was impossible for us to determine the speed of nervous transmission—an affirmation as imprudent as are all affirmations which proscribe formal conclusions to the science of the future.

Well, as I say, just two years after this unfortunate prophecy of Johannes Muller, Helmholtz ascertained that, if you determine the time of response by stimulating a nerve at a given point, you can determine the rate of transmission by stimulating the same nerve at a measured distance, say a decimetre, above that point; for, as in this case, the response will be delayed, the period of delay measures the rate the nerve impulse has taken to travel over ten centimetres. Since then countless determinations have been made of the speed of the nerve-current. It has been found to vary with the temperature and with the character of the nerve stimulated; it is less rapid in the nerve-centres than in the peripheral nerves, less in cold-blooded than in homœothermic (or so-called warm-blooded) animals. But it never differs much from thirty metres per second.

Moreover, this nerve current has been found to be always transmitted in both directions from the point of stimulation. I will not dwell on the exceedingly technical proof of this law, but merely recall the fact that whether the nerve stimulated be motor or sensory, the nerve current travels both ways along it, both towards the periphery (skin, muscle, &c., as the case may be) and towards the central nervous system.

A most important fact is that an electrical disturbance accompanies every stimulation of a nerve. If in the undisturbed condition we place the poles of a circuit with an interposed galvanometer at two points of a nerve (one on its surface, the other on a cut end), to ascertain its electric condition, we find that there is an electric tension between them, that there exists in the nerve a certain current. If we then stimulate the nerve, the current is seen to be reversed, or, as we say, undergoes a "negative variation," and the rate at which this change is transmitted is sensibly the same as that of the nerve-wave. Matteucci, Du Bois Reymond, Bernstein, Waller have studied all the complex details of this process; so that it now ranks among the best known phenomena in physiology.

We ask:—Are there, concurrent with this electric variation, modifications in the chemical and thermic condition of the nerve or nerve-centre? Yes, in all probability; but the answer is not certain. Schiff thought that by stimulating the retina of the pigeon he induced a change in the temperature of the brain. Mosso also thought he could find localised areas of higher temperature in the brain after stimulating certain points; but the elevation of temperature is, to say the least, of low intensity and difficult to determine.

In this rapid sketch, the last law I have to formulate is *the law of the integrity of the organ*. The physical and mechanical union may be maintained; but if its organic continuity be severed as by a cut, even when the two ends are joined up, the nerve-current is no longer transmitted.

IV.

Several hypotheses may be put forth as to the nature of this phenomenon.

Formerly, when words were accepted in place of facts, it was said that there was a transference of "animal spirits" (a conception due to Descartes); this was the current expression in the sixteenth, seventeenth and eighteenth centuries. A curious apparent confirmation was found in Richard Lower's experiment: he tied a nerve, and saw that it swelled above the seat of ligature; this, said he, was the accumulation of the animal spirit, arrested by the tightened thread. The experiment was a perfectly valid one; and you see that from it it was possible to deduce conclusions that were perfectly false. The swelling was due to the increase of blood pressure and to inflammation.

We may drop this old hypothesis of "animal spirits," and pass to four theories put forward to explain the nature of the nerve-current.

(1) *Mechanical Hypothesis.*—If, as is probable, the semi-fluid protoplasm of the nerve-cell and its prolongations form one continuous whole, it follows that a mechanical disturbance of this liquid mass will be propagated to a distance along the whole length. Suppose a capillary tube filled with mercury; a disturbance of the mercury will be propagated the length of the tube, so that at the far end we perceive a vibration started from the opposite end. In this case the nerve-wave would be the molecular disturbance of a liquid enclosed in a capillary tube.

This hypothesis would afford a fair explanation of the electrical phenomena involved; for we know that the friction of a fluid in a capillary tube produces electricity. However, this mechanical explanation presents certain difficulties, for in a capillary tube the narrower its calibre the more rapidly the vibration is damped; consequently, it is hard to conceive that a vibration could be transmitted so as to be appreciable at the far end of a tube one or two metres long. It is true that we can form no supposition as to the absolute measurement of such perturbation; and perhaps almost infinitesimally small forces are adequate.

On the other hand, the electric disturbance that accompanies the nerve-wave does not lose intensity as it travels: on the contrary, Pflüger and other physiologists declare that it grows like an avalanche. Hence, taking all considerations into account, the nerve-wave is a phenomenon other than a mechanical vibratory molecular disturbance of the semi-fluid protoplasm.

(2) *Chemical Hypothesis.*—The transmission of the nerve-wave along a nerve has been compared to the explosion of a train of powder, or of mixed gases in a tube; and this you know is transmitted relatively slowly, nay, very slowly if the tube be of capillary dimensions. If, say, an explosive mixture of oxygen and hydrogen be contained in a very narrow tube, and a flame or spark applied at one end, the combustion will not be instantaneous, but will pass as a wave along the tube, and that a very slow wave, if the tube be narrow.

What at first sight would give some plausibility to this hypothesis is the fact that a very feeble stimulus may call forth a very strong response. Take the amount of energy received by a surface of 1 sq. cm. from a candle 300 metres distant; it is 1/10,000 millions of the total light-giving energy of the candle, a quantity whose absolute value is in one sense a negligible quantity, but which is adequate to give a sensory stimulus to the retina. The retina must be supposed to contain a quantity of accumulated energy susceptible of explosive liberation, so that the amount freed would be far in excess of the energy of the stimulus.

But there is one very serious objection to this hypothesis; it demands that the explosive tissue should be reconstituted afresh immediately after each explosion. It is not easy to see how the moment after the explosion, in the hundredth of a second, the nervous substance could be reconstituted afresh. Though serious, the objection is not irrefutable, for we know too little of the speed or slowness of the chemical changes of the organism to use this as an argument against any theory whatever.

(3) *Electrolytic Hypothesis.*—Certain chemical changes are characterised by their allowing of an immediate reconstruction after their occurrence, such are the phenomena of electrolysis. When a current passes through a saline solution, it is believed that, as it passes along, the salt is decomposed from place to place, and immediately reconstituted as soon as the current has passed. The passage of the electrolytic current is sometimes exceedingly slow. There is nothing to prevent our accepting some such explanation of the nerve-wave; it has the advantage that it can be brought more or less into harmony with the chemical and the electrical hypothesis, and can indeed reconcile them.

(4) *Electric Hypothesis.*—This supposes that an electrical current passes along a peculiar form of conductor—the nerve. The chief objection that has been urged, in the extreme slowness of the nerve-wave—30 metres per second—as against 700 million metres, the alleged rate of electricity. But this omits to take account of the fact that electricity travels at this speed in good conductors only. Electricity passes along a conducting wire, ten thousand, a hundred thousand, times as fast as along a badly conducting tube; it is only reasonable to admit that the transport of electricity may be enormously retarded in a capillary tube filled with a very bad conductor. It has also been urged that, since different nerves can transmit very different sensations simultaneously to the different parts of the nervous system, there should be a blurring and confusion from the imperfect insulation of the tubes if it were electricity that they conducted.

"How, for instance," we are asked, "could nerve-cells of the cord and the brain communicate their electrical disturbances in narrowly localised groups with that extraordinary precision, without the neighbouring cells feeling the effect?"

We do not attach much weight to this objection because, in the first place, the axis cylinders have an insulating covering of myeline, as have also the cells of the brain; and again, in electric fishes, electric shocks one hundred thousand-fold as strong pass between certain organs without the rest being at all affected, so perfect is the insulation.

Thus the hypothesis that the nerve-wave is an electric phenomenon is fairly satisfactory, especially if we admit that it resembles electrolytic action.

Certainly we must allow for the unforeseen ; we must recognise the possibility that, perchance at no very distant date, we may receive the formal demonstration of fundamental differences between electrical and nervous vibrations, and have to admit that the latter possess special characters which differentiate them from all known classes of vibrations.

V.

I now come to a different order of facts, on which I will speak more fully, for I have to deal with my own researches, some, indeed, as yet unpublished. These I carried on in collaboration with M. André Broca ; they are, I think, of a character likely to shed light on some of the conditions of the nerve-wave. True, they tell us nothing of the actual nature of nerve-vibration ; but they will allow us to deduce the form of the nerve-wave.

Our experiments were made on the nerve-centres, not on the peripheral nerves ; as a matter of fact, we believe that the laws which we have discovered for the one will apply to the other, and Charpentier's recent and most ingenious researches confirm this assimilation.

We must go back to the very definition of a vibration. We have seen that it is a movement of oscillation, an object is removed from a position of equilibrium and comes back to it again. Such is a *simple oscillation ;* in a *complete wave*, after returning to the position of equilibrium from the furthest point, it passes that position and only returns after a certain traverse in the opposite direction.

If we call the first simple oscillation from the position of equilibrium the *positive phase*, the second oscillation is regarded as the *negative phase* of the complete wave. Now the phenomenon is no simple one ; the return to equilibrium is not

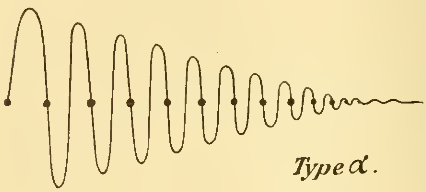

FIG. 1.

durable, and if no new condition intervene the vibration will continue. Were there no friction or resistance the vibration would persist indefinitely ; for there is no reason for the motion to stop, and the pendulum, to take the very simplest case, would never return to rest at its original position of stable equilibrium. To stop the vibration there must be some deadening or *damping* process.

Physicists have studied the modes of damping, and find that they are divided into three types.

Type $\alpha$ is that of a pendulum, a vibrating string, or the waves of liquid when a stone enters the water. A series of complete waves follow with smaller and smaller oscillations, and the vibration dies out by the gradual decrease of the waves—secondary, tertiary, &c.—which followed the primary wave. This type of damping is, as we have said, due to the resistance of the medium consuming part of the energy ; for, theoretically, a vibration once started would never stop. You are familiar with the fact that a pendulum continues to swing much longer in vacuo than in the air, and I need not dwell further on this point (Fig. 1).

Type $\beta$ shows a very different character in its damping. After the pendulum has completed its first phase and passed the point of equilibrium, it meets a certain obstacle to its return point ; it only swings back again very slowly thereto, and on reaching it it cannot pass beyond it. Indeed, from diverse theoretical considerations it may be proved that it never returns absolutely to the point of equilibrium ; it approaches it indefinitely without ever reaching it ; in short, ABA′ is an asymptotic curve of which AA′ is the asymptote. Later on we shall see what conclusions may be drawn from this as to the nature of the nerve wave. Suffice it now to demonstrate the form of the wave with this type of damping. Practically, stable equilibrium is reached sooner than by type $\alpha$ : indeed, this is the type of damping used in the transmission of signals by submarine cables ; where it is necessary to prevent each signal from producing a whole series of swings of the galvanometer needle, and to obtain as rapidly as possible its return to equilibrium and rest (Fig. 2).

Type $\gamma$ remains to be described : here the pendulum, after being moved from the point of equilibrium, returns only very slowly to that position ; this it does, for example, when hanging in a very dense medium. In this type of damping, as in $\beta$, there are no consecutive secondary and tertiary vibrations ; nay, more, the damping is here so complete that there is no negative phase, only a simple oscillation. This curve is also asymptotic, and the return never reaches the primitive state of equilibrium (Fig. 3).

We see at once that the form of the wave is determined in each case by the type of its damping, and our experiments have

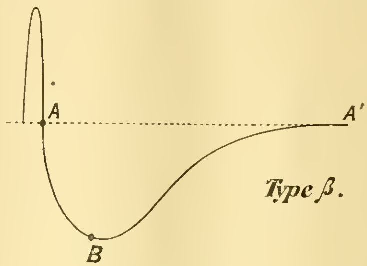

FIG. 2.

enabled us to determine the character of the damping of the nerve-wave. We might have set type $\alpha$ aside *à priori ;* it would have been unreasonable to suppose it. If to wave I succeeded waves 2, 3, 4, &c., a single stimulus would produce a whole series of responses ; now this is not the case with the nerve. Hence the damping must be on the type of $\beta$ or of $\gamma$. But obvious as these considerations are when once stated, we did not reach them *à priori ;* it required actual experience to enlighten us ; so true is it that in science, at least in physiological science, experiment is more fertile than dialectic.

VI.

The following were the methods by which we determined the form of the nerve-wave. I will not describe our research in order of time ; I shall only select some of the simplest, the most demonstrative, experiments. We know that but rarely are the earlier experiments one or the other ; they are complex and

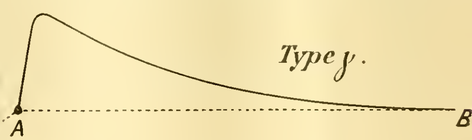

FIG. 3.

slow, and it is only by degrees that one learns how to simplify them and make them direct.

A dog is anæsthetised by the injection of a sufficient dose of chloralose into the veins (0·1 gramme to the kilo. of live weight), and electrodes are applied to the surface of its head. We can now observe the effects of an electric stimulus on the cerebral cortex under excellent conditions. The electrodes can be fixed immovably, so that the same part of the cortex is always stimulated ; and the effects of the stimulus are always localised in the same muscles. If we repeat the same electric stimulus, supplied by a secondary current from accumulators, always of the same suitable intensity, we find that each successive electric shock, repeated at intervals of one second, calls forth a regular and equal muscular contraction in response. This regularity is complete, and if the conditions of circulation and respiration are kept satisfactory for one, two, or even three hours, we have a

series of regular contractions which are easy to register. But when we quicken up the succession of the stimuli, there comes a time when the responsive contractions lose their regularity: a normal contraction is followed by a small one, a large one by a small one, and so on. Thus we can determine at what rate of intermission of the successive stimulations their responses lose their regularity: we find that when the intervals between the induction shocks are less than the tenth of a second, at the normal temperature of the body (39° C. for the dog) the contractions are no longer regular. Matters now go on just as if, after the large normal contraction, there were a *refractory period*, during which the excitability of the nervous system is lowered.

Marey, in his beautiful researches on the heart, had previously showed that after a contraction of the heart there is a short refractory period during which it is not excitable. So, after the stimulation of the brain, a period not exceeding 1/10″ intervenes during which it is not excitable, a refractory period.

Whatever be the temperature of the animal under experiment, we always find this refractory period, which, however, becomes easier to measure when the temperature falls, for then it lengthens out enormously. It is 0·1″ at 39° C.; 0·18″ at 35° C.; and if we chill the dog greatly, to 30° C., it rises to 0·6″. Hence it is advantageous to chill warm-blooded animals for the purpose of these observations.

It is noteworthy that this refractory period can be demonstrated otherwise than by electrical stimuli; mechanical shocks will also serve the purpose. If we poison a dog with chloralose, it becomes extremely sensitive to every mechanical disturbance. The least jolt of the table on which it lies makes it start, and though insensible, and not susceptible to pain, it responds to every jolt by a start. We can register these starts; and if, working with a dog cooled to 30°, we repeat the jars at intervals of less than half a second, the starts lose their regularity. Under these conditions a big start is followed by a small one, and *vice versâ*, though the jolts of the table are quite equal. In successful experiments we may even find the second shock absent; so that if the times of the successive jolts be noted as $a$, $a^1$, $a^2$, $a^3$, $a^4$, &c., we only get responsive shocks at $a$, $a^2$, $a^4$, &c.

The physicists have given the mathematical and mechanical explanation of this phenomenon, which they call the "*synchronisation of the oscillators*"; it has recently formed the subject of an important memoir by Cornu, which, however, I cannot describe even in abstract here. Suffice it to say that these refractory intervals presuppose the existence of a refractory period, of a *negative phase* in the nerve-wave.

The synchronisation of the nervous oscillation with that of the stimulus can only be explained by the assumption of the vibration of an apparatus (the nervous apparatus) possessing a proper period of its own, and with which we regulate and adjust the proper period of a second apparatus (the stimulating apparatus).

Thus, by this method we have succeeded in determining the duration of the nerve-wave; and we may state that this is 1/10″, an exceedingly slow rate as compared with electric or luminous vibrations, whose period is measured in 1-one thousand millionths or billionths of 1″.

We can also determine the form of the wave, and we find it approximate to our type $\beta$. If we consider the period of 0·1″ which elapses between the stimulus and the completion of the nerve-wave, we find that it may be divided into two periods: (A) in the first part a second stimulus will augment the effect; it is the "*phase of summation*" or *positive phase* of the wave. (B) in the second period the stimulus produces a decreased effect; this is the "*phase of subtraction*" or *negative phase*. Now the phase of summation is very small, scarcely more than 0·01″, while the phase of subtraction is very long, nearly 0·09″; but I must not go into more detail on this point, lest I should enter on matters too strictly technical, which I prefer to avoid.

## VII.

In cold-blooded animals the phenomena are quite different; and recent experiments have shown us how imprudent it would have been to generalise too hastily. If, indeed, we repeat the experiment on a tortoise, we find results apparently contradictory of those I have just related to you. A stimulus following another always appears to produce a stronger response than its predecessor. *There is no refractory period, there is a summation phase all the time.* Of course I mean that the stimuli must not be too far apart; if the interval exceeds 2″, two successive stimulations of the brain call forth equal contractions. But with intervals of less than 2″ summation phenomena are always observed, the more marked as the interval between successive stimuli is decreased. Finally, as I say, there is no refractory period.

Hence we may conclude that in cold-blooded animals (at least in the tortoise) the nerve-wave has a different form from that of the dog; after the displacement from the primitive position of equilibrium there is only a slow and gradual return, without any such backward oscillation as explains the negative phase in the dog. This form of wave we have described under the third type of damping (type $\gamma$) (Fig. 3).

This type of wave is exceedingly slow; if the tortoise be chilled by the use of suitable stimuli, we can estimate its duration at 2″. But with normal animals at 15° C. the period may perhaps be taken as 1″.

This difference of tenfold is not surprising; there was no antecedent improbability in conceiving that the nervous phenomena of a tortoise are ten times as slow as those of a dog.

## VIII.

The fact that the nerve-wave lasts one-tenth of a second in the dog, as it probably does approximately in man, opens up a field of interesting considerations which confirm the results of direct experimental physiological observation.

If the nerve-wave lasts 1/10″, it follows that two nerve-waves cannot remain completely dissociated when they follow at shorter intervals than this. Suppose that a stimulus of light calls forth a nervous reaction, a sensation; this reaction, this sensation, will last at least one-tenth of a second; and consequently when a fresh stimulus follows on the first, its sensory response will not be clearly distinct unless this interval at least separates the two. If they follow more closely, they will blend together. Well, a classical and well-known experiment tells us that we cannot receive more than ten or eleven distinct retinal sensations in a second. At eleven per second, we already experience *flickering*; that is, the images are becoming confused. This, the persistence of retinal images, is the familiar principle of the cinematoscope, which has latterly received such elegant popular applications on a large scale.

No such exact studies have been made on the confusion of acoustic or tactile stimuli. But the very remarkable and concordant results of retinal sensation are enough to prove that the cerebral vibration consequent on a stimulation of the retina has a period of 1/10″.

If we turn to the case of a voluntary movement, determined also by a cerebral nerve-wave, we find the same figure. Schäfer in 1886 determined that distinct successive muscular contractions, voluntary or called forth (as reflexes) by electrical stimuli, very rarely exceeded 11–12 per second. Herringham found a frequency of 9–12 in pathological tremors. In the case of shivering from cold, I have determined frequencies of 10, 11, 12, 13 per second. Griffiths determined a frequency of 10 for the muscles of the thumb, and 14 for those of the arm. The Swedish physiologist, Loven, found that the electric oscillations of the cord determined by very frequent stimuli were only 8–10 per second.

Yet we know that if muscles be stimulated directly by rapidly alternating currents, they will contract with much greater frequency. The numerous physiologists who have studied the subject are agreed that we may thus determine as many as thirty or forty muscular contractions per second. If then we can only produce some ten voluntary contractions in the time, the cause lies, not in the muscles, but in the cerebral apparatus, which cannot vibrate more rapidly. Its period is 0·1″; it can only vibrate ten times in a second—can only order ten distinct voluntary movements of the same muscle in a second. It is not that the muscle cannot obey, but that the central nervous system cannot give its orders at a greater speed.

Now I will give you an experiment that you can all try for yourselves, which proves most clearly that the vibration of the nerve-centres determining a psychological phenomenon lasts about one-tenth of a second. When I thought over the various modes of obtaining a very rapid muscular motion, it occurred to me that perhaps the best was the articulation of some sentence pronounced with the greatest possible rapidity. We may admit that every syllable articulated represents a distinct muscular contraction, and consequently a distinct effort of the will. On trying what was the greatest speed of articulation, I found it

was eleven syllables a second; and, indeed, at this speed all the syllables were not perfectly articulated.

This experiment has no particular interest in itself, for it only confirms the results of Schäfer, Lovèn and Griffiths, that repeated voluntary muscular actions have a speed of some ten or twelve per second. But, if we modify it slightly, its bearings are much wider. If instead of *vocally* articulating the syllables, we *think* them and articulate them only *mentally*, we exclude muscular action from any share in the process, and the rapidity of the mental articulation will be the index of the cerebral rhythm, not the muscular. Well, I found, as any of you can do with the help of a good seconds watch, that the mental articulation gives exactly the same figure as the vocal; that is, ten or eleven syllables per second.

We come to the interesting and relatively unforeseen conclusion that the cerebral phenomena of feeling (in the retina), volition (on the muscles), and thought (in mental articulation) cannot be repeated faster than twelve per second, and that they last about one-eleventh, or in round numbers one-tenth, of a second; the isolated sensation, the isolated act of will, the isolated intellectual process, have all the same minimum duration.

Placing this result next to our determination of the period of the nerve-wave, we conclude that there is here more than a mere coincidence; it is an *à posteriori* proof of our hypothesis as to the period of the nerve-wave.

From the psychological point of view this leads us to very important deductions. Of course we can conceive the second to be divided into hundredths, millionths, billionths; but these divisions have no relation to our direct consciousness. Our consciousness can only perceive much longer intervals. Our cerebral organisation determines narrow limits for our appreciation of time. We may therefore define the *psychological unit of time*, the irreducible unit, as *that minimum duration of time which is appreciable to our intelligence*. This is, indeed, susceptible of further theoretical subdivision; but such subdivisions correspond to no real mental image.

We may say, in other words, that the minimum time which our consciousness can directly apprehend is, in round numbers, one-tenth of a second.

"Swift as thought" is an everyday phrase; but you see thought is not very swift, after all, if we compare it to the enormous frequency of the vibrations of light and electricity.

Sir William Crookes, one of your most illustrious presidents, spoke of the relativity of our knowledge in his recent address; he alluded to the cruel imperfections of our animal nature. For us there exists no time-interval shorter than one-tenth of a second; and yet during this short interval, within which our gross intellectual apparatus cannot penetrate, who knows what sequences of phenomena may go on, which we could perceive if our nervous system had a shorter period of vibration? Then would phenomena which we perceive as continuous reveal their true character of discontinuity; those molecular vibrations which to us do not appear as vibrations would take on their real aspects. In a word, our time-unit, which is so different from the units of many phenomena of matter, makes us live in one perpetual illusion.

One more point I wish to touch upon is interesting in many respects. Let us come back to the diagram I gave you above to show the mode of damping of the nerve-wave. I told you that the original level is never regained when the system is damped to a position of rest; it approaches the level indefinitely but never reaches it. Practically speaking, equilibrium is reached at the end of the tenth of a second; physically and physiologically speaking, everything is set in order; the nerve-wave is ended, and the return to equilibrium is total. But if we deal with infinitesimal quantities this return is not complete; so that if we imagine an apparatus capable of appreciating infinitesimal quantities, it would show that, as the mathematical theory predicts, the return to equilibrium is never complete or absolute.

Well! we may fairly suppose that consciousness is alive to this infinitely small quantity, and that the impossibility of the complete return to the primitive equilibrium accounts for the strange phenomenon, unknown in the inorganic world, which we call *Memory*.

After a nerve-wave, the neuron is no longer in the same state as before; it retains the memory of the wave, and this makes it now other than what it was. I pronounce the vowel "A"; one-tenth of a second later I can pronounce some other vowel, for my nervous system has returned to equilibrium; but this return, however, is not complete, for the memory of the "A" which I pronounced persists, and will persist indefinitely. The primitive condition will never recur, whatever happens. In time the memory of the vowel "A" will gradually fade, but it will never be effaced. A nerve-wave of the brain is never completely extinguished.

The fact is that we are here on the confines of two totally distinct worlds: the world of physics and the world of psychology. What is infinitesimally small in the physical world may possibly be infinitely great in the psychological world. The residues of nerve-waves, the asymptotic prolongations of curves, may be neglected by the physiologist and the physicist; they are not negligible to consciousness.

Consciousness distinguishes them from the strong vibrations actually going on, which it recognises as "the present"; but the waves that are passed still exist for consciousness, never perhaps to be annihilated.

Assuredly this is but an hypothesis, perhaps an analogy, a comparison, rather than an hypothesis; but it is none the less interesting to note how far the physiological theory of the damping of the nerve-wave is in agreement with the grand psychological fact of memory, which it is scarcely possible to explain in any other way.

IX.

Thus the nerve-wave in its form and period, and in the mode of its damping, is comparable with the various waves of the unbounded universe in which we live, move and have our being. But this resemblance must not lead us away from the recognition of the abyss that separates the nerve-wave from all the other phenomena within our reach. The vibrations of the forces scattered about us are—at least with the greatest probability—blind phenomena, which know not themselves, which are the slaves of irresistible fatality. The nerve-wave, on the contrary, knows and judges itself; it is self-knowing or self-conscious; it can distinguish itself from the world which surrounds it and shakes it.

Since it possesses intelligence—for intelligence and consciousness are synonymous terms—it is susceptible of perfectibility; it is capable of right reasoning and of wrong reasoning; it can attain a moral ideal forbidden to those brute forces which follow their fated course; it can conceive the idea of truth and justice when it is a question of defending the innocent, of establishing brotherhood among men.

Consciousness, intelligence, the making for higher perfection—these are characters that have nought in common with the characters of other waves; they seem to be phenomena of another, a higher order. This vibration, whose physical conditions we have studied, enters into the domain of morals; and this fact establishes its essential difference from all other vibrations.

Assuredly the prodigiously rapid and regular undulations of light, and of electricity, appeal right justly to our admiration; but nothing is so admirable as this disturbance of the nerve-cell, which is self-knowing, self-judging, self-transforming, which strives to amend itself, and which from the stimuli which strike it can deduce some of the laws ruling the vast universe distinct from it. The nerve-wave of man—himself the last result of evolution—is the most perfect term of the things and of the beings which it is given to us to know.

Vast as is the world, mighty as are the fires of the infinite stars, the intelligence of man is of a higher order than these; and I would fain exclaim with the great philosopher, Immanuel Kant: "More than the starry heaven above my head, one thing fills me with admiration: the moral law in the heart of man."

## *ZOOLOGY AT THE BRITISH ASSOCIATION.*

ON the opening day (Thursday) only the President's address was taken, and the Section then adjourned with the object of hearing addresses in other Sections which were of biological interest. The total number of papers brought before the Section this year was not as large as usual, but they extended over a wide range of zoological subject-matter, as the following outline programme shows:—

Friday morning, morphological papers; Friday afternoon, papers on entomology and mimicry; Saturday, marine biology; Monday, morphology, &c.; Tuesday, papers on sea-fishery questions. The usual reports upon investigations in progress were also submitted.

The morphological papers on Friday were as follows :—

(1) J. J. Lister, on *Astrosclera willeyana*, the type of a new family of calcareous sponges. This remarkable new sponge was brought home by Dr. A. Willey from Lifu in the Loyalty Islands. It has a continuous calcareous skeleton formed by the union of numerous polyhedral spicules to form a branched mass, between which run the soft parts with the system of canals. There are very minute ciliated chambers, and the ciliated cells do not appear to have the usual collars.

(2) Prof. Johnson Symington, on the morphology of the cartilages of the monotreme larynx. The thyroid cartilage of the monotremes (*Ornithorhynchus* and *Echidna*) agrees with that of the higher mammals in consisting of a single cartilaginous mass, but differs in the details and relations of its anterior and posterior cornua. Both the ontogeny and the phylogeny of the mammalian epiglottis support the view that it is a single median structure, and not, as Gegenbaur supposed, the result of fusion of two lateral elements.

(3) N. Bishop Harman, the palpebral and oculo-motor apparatus in fishes. Seventy species of fishes were examined. The simplicity or complexity were not found to agree with differentiation in phylogeny, nor with any scheme of classification, nor in relation to habitat. The source of the complex musculature of the eyelids of Selachians was traced to the branchial musculature of the spiracle, and this was further shown by the inverse ratio existing between the condition of spiracle and nictitating membrane. In those fish in which the latter is at its highest development the spiracle is absent, and *vice versâ*. The condition of the orbital sac, of the supporting rod of cartilage, of the eye-muscles, and of other neighbouring structures in the eyes of various groups of fishes was discussed.

(4) Prof. R. J. Anderson, on the pelvic symphysial bone of the Indian elephant ; and a few notes on rhythmic motion.

(5) C. Dawson and S. A. Woodhead, on the crystallisation of beeswax, and its influence on the formation of the cells of bees.

On Saturday, when some of the zoologists from the French Association visited the Section, a few papers on marine biology likely to prove interesting for joint discussion were taken. Mr. W. Garstang brought forward a first report on the periodic investigation of the plankton and physical conditions of the English Channel during 1899. These investigations have been carried out at regular quarterly intervals during the year, from a steam-tug ; and the observations were made at certain fixed localities along lines between Plymouth and Ushant, from Ushant towards the 100 fms. line, and off the entrance to the Channel. Observations of the water temperature (with deep-sea reversing thermometers) at various depths, and of the salinity (with Mill's water-bottle) of the water were taken ; and collections of plankton were made with an effective closing tow-net specially devised by Mr. Garstang to replace the pump and hose method, which had proved unsatisfactory. This new net, and also that of Dr. C. G. J. Peterson for the quantitative estimation of plankton, were on exhibition and with the rest of the apparatus were shown working. Mr. Garstang's investigations in the Channel are not yet completed, and two further series of observations are still to be made. The record so obtained will be of high value in both marine biological and hydrographical inquiry. Prof. Lankester and others took part in the discussion, and one of the visitors, Baron Jules de Guerne, explained the somewhat similar observations he had been making from the Prince of Monaco's yacht *Princesse Alice*, and described the closing nets he employed. The reports upon the Naples and Plymouth biological stations were also submitted.

On Monday the following papers were taken :—

(1) J. Graham Kerr, the development of *Lepidosiren paradoxa ;* and a note on the hypothesis of the origin of the vertebrate paired limbs. Mr. Kerr had been sent by the University of Cambridge with an expedition in search of *Lepidosiren* to the rivers and swamps of Gran Chaco in Paraguay ; and he gave an interesting summary of the life-history of this important type.

(2) Dr. J. F. Gemmill, on negative evidence regarding the influence of nutrition in determining sex. Dr. Gemmill shows that certain fixed species of marine animals are under very different conditions of nutrition from the very earliest period, according as they are high or low on the shore, and yet the proportions of the sexes remain unchanged—indicating that in such forms nutrition has no effect in determining sex.

(3) F. P. Morena and A. Smith Woodhead, exhibition of and remarks on a skull of the extinct Chelonian *Miolania* from Patagonia, along with an exhibition of newly-discovered *Neomylodon* remains from Patagonia—a most interesting and important exhibit of these remarkable remains.

(4) G. E. H. Barrett-Hamilton, the fur seals of the Bering Sea. An account of their habits and condition.

The rest of the afternoon was occupied with reports of Committees, which will be noticed below.

On Tuesday, Sir John Murray read a paper on Dr. Peterson's experiments in the Cattegat, with the marking and measuring of plaice in order to determine distribution and growth, and on plaice culture in the Limfjord. By transplanting young fish from the North Sea into the richer feeding grounds of the shallow fjord, it was found that from April to November they increased to five times their original weight. The cost of transportation was one-sixth of a penny per fish, and the price obtained for a fish so fattened was 4*d*.—a notably successful attempt at economic fish culture.

Mr. W. Garstang gave an account of his experiments at Plymouth on the artificial rearing of young sea-fish. In this Mr. Garstang has, so far, been very successful ; and has succeeded in rearing about 50 per cent. of his larvæ through their critical stages to the complete adult organisation. They are fed on plankton, and are kept in "plunger" jars with not more than five larvæ to a gallon of water.

Dr. James Murie gave an account of the Thames Estuary : its physico-biological aspects as bearing upon its fisheries. These papers gave rise to some discussion on marine fish-culture.

Prof. McIntosh, finally, gave a paper on the occurrence of the grey gurnard (*Trigla gurnardus*, L.), and its spawning in inshore and offshore waters. He shows by a monthly examination of the statistics that this important fish does not begin to move into the inshore waters for spawning purposes until after February, and attains its maximum in May. He does not consider that a maximum as late as August in some years can be taken to indicate a second spawning migration, as supposed by the Scottish Fishery Board. Spawning goes on from April to September.

The Reports of Committees submitted to the Section were as follows :—

(1) The Naples Zoological Station.—The British Association table has been occupied by Dr. H. Lyster Jameson, who gives a summary of his work upon the anatomy of certain Gephyrea and allied vermiform organisms. The usual statistics and other information in regard to the station during the year are also given.

(2) Investigations at the Plymouth Marine Laboratory.—This contains two short papers, one on the embryology of the Polyzoa, by T. H. Taylor, and the other on the rearing of larvæ of Echinidæ, by Prof. MacBride. Mr. Taylor's observations were made on the larvæ of *Bowerbankia*, which he successfully carried through their fixation and metamorphosis on strips of celloidin. MacBride found at Plymouth that the larvæ of Echinids would only live in pure water brought from outside the breakwater. He discusses the difficulties, and the conditions necessary for successful rearing of larvæ.

(3) Zoology and Botany of the West India Islands.—This is the final report, and consists of a list of the publications of the Committee. The material which still remains unworked out has been presented to the British Museum.

(4) Zoology of the Sandwich Islands.—This ninth report shows what has been published by the Committee during the year, and gives the plans for further exploration in the Islands in conjunction with the Honolulu Museum.

(5) Bird Migration in Great Britain and Ireland.—The labour of working out the numerous records obtained from lighthouse-keepers is still being continued by Mr. Eagle Clarke, and a conclusive report is not yet possible.

(6) Zoological and Botanical Publication.—The Secretary of the Committee is in correspondence with editors of academical and periodical publications, and the results will be reported on at a future meeting.

(7) Index animalium.—This great piece of work is still being carried on by Mr. Sherborn, who has indexed about 1500 volumes during the last year. The first section of the Index, dealing with 1758–1800, will soon be ready for publication.

(8) Pedigree Stock Records.—This report is drawn up by Dr. Francis Galton, and deals with the production of photographs, under standard conditions, of prize-winners at shows of pedigree stock, in order to have exact trustworthy records of ancestry.

(9) A circulatory apparatus for experimental observations on marine organisms. The work has been carried out by Mr. F. W. Gamble at the Piel Sea-Fish Hatchery on the Lancashire coast; and the observations chiefly dealt with the changes in colour, and the mechanism of colour physiology in the Crustacean *Hippolyte varians*.

On one of the afternoons Mr. J. W. Woodall took a small party of zoologists to sea in his yacht *Vallota*, to witness the trial of Mr. Garstang's new tow net, which can be opened and closed in any depth of water. In addition to the actual proceedings in Section D, it may be noted that there was a good deal in several of the other Sections that was of zoological interest.

## THE SEVENTH INTERNATIONAL GEOGRAPHICAL CONGRESS.

AT the close of the Sixth International Geographical Congress in London in 1895 it was decided that the next meeting should be held in Berlin in 1899, under the auspices of the Berlin Geographical Society. This meeting, with its attendant festivities, has just been concluded. Although the actual sittings of the Congress extended only from September 28 to October 4, the proceedings began a week earlier and were continued more than a week later, by a series of geographical excursions to different parts of the German Empire. Taken as a whole the Congress must be pronounced not only successful, but brilliantly so; it presents a sort of climax in respect of grandeur to the preceding meetings, and suggests that the time has now come for reconsidering the general plan of such gatherings, and starting afresh on lines of plainer living, if not of higher thinking. Here, however, we have only to sketch the work of the Congress just over, not to suggest the plan of its successor.

The Council of the Berlin Geographical Society had the entire charge of the organisation, and by the usage of previous meetings the President of the Society, Baron Ferdinand von Richthofen, professor of Geography in the University of Berlin, was President of the Congress. The personal efforts of Baron Richthofen were unceasing before and during the meeting, and as no German geographer is better known or more widely respected at home and abroad, the accident of his presidency of the Society was singularly fortunate for the success and *éclat* of the Congress. He was supported as secretary by Hauptmann Georg Kollm, and a number of younger geographers who formed a staff of efficient assistant secretaries, but whose names were not brought before the members. Similarly, the various honorary officials—vice-presidents, members of committees, &c., whose names had appeared in circulars sent out some months before the meeting—remained unknown to most of the members, who had left their early circulars at home. There were general programmes, printed in German, English and French, detailing the work for each day, and a supplementary programme of entertainments in German only, with additions and alterations to the list of papers; but there was no daily journal giving a clear view of the work of each day, with the names of presiding officers and a summary of the work of the day before, as at the London Congress. German also was the one language used in the general business, all announcements were made in German only, almost all the notices exhibited were in German and sometimes even in the German script, which can scarcely be looked on as an international character. In London the three languages were used for every written or printed notice and every important verbal announcement. The abstracts of papers, which were circulated daily, were printed in the language of the author only. The foreigner, unversed in the German language and unused to German customs, was somewhat at a disadvantage throughout, both in scientific meetings and at social functions.

These minor matters apart, the organisation left nothing to desire. The grand building of the Prussian Chamber of Deputies, generously lent to the Congress by the Prussian Government, formed a perfect home for the member. A "depositorium," bearing the number of his ticket, received all communications intended for him, an admirably-conducted cloakroom relieved him of hat and coat, and restored them with a swiftness and certainty that seemed magical to the frequenter of British scientific gatherings; a vast refreshment room could serve breakfast, lunch and supper to the whole Congress simultaneously; picture post-cards (more essential than food to the German visitor) were on sale in every room, even in the Great Hall while papers were being read; desks were provided for issuing tickets, badges and the many offerings of books, maps, &c., presented by institutions and firms; while the luxurious reading- and writing-rooms of the Prussian Deputies were thrown open absolutely without reserve. As an example of international hospitality, the installation of the Congress was memorable and unique. Perhaps the best managed of all the hospitable arrangements was the Ladies' Committee, specially charged with the care of the lady associates of the Congress, which carried out its work with most satisfactory diligence and completeness.

The Congress commenced informally in true German style by the members dropping in as they arrived on the evening of Wednesday, September 27, to the restaurant of the House of Deputies, where they sat at supper or wandered through the various halls, greeting old friends and forming new acquaintances. Next morning at ten o'clock the formal opening took place with much dignity, the gentlemen appearing in evening dress or uniform with a profuse display of orders. Prince Albrecht of Prussia welcomed the Congress in the name of the Emperor; Prince Hohenlohe, the Imperial Chancellor, welcomed it in the name of the Empire; Herr Studt, the new Prussian Minister of Education, in the name of the kingdom of Prussia, the speeches of these great personages being received in solemn silence. The Burgermeister of Berlin then welcomed the members in the name of the city, and applause, which was not stinted to subsequent speakers, then began. The welcome was responded to by a few of the most distinguished foreigners. Baron Richthofen read his presidential address, on the progress of geography in the nineteenth century; Sir Clements Markham, as president of the sixth Congress, gave a short address, resigning his office and presenting the report of the London Congress. Vice-presidents and chairmen of the different sections were nominated, and the formalities were over.

It is unnecessary to detail the social accompaniments of the Congress. The Imperial Chancellor gave a small dinner and a large reception to the foreigners and the more prominent German members. The city of Berlin gave an admirably conducted dinner to the whole Congress in the Zoological Gardens. The Berlin Geographical Society also entertained all the members to a reception and supper, and there was a special performance in the Opera House.

It is impossible to pass without remark the magnificent hospitality of Hamburg, where over 500 members of the Congress were received by the local Geographical Society, and carried through two days of uninterrupted festivity. The Senate opened the State rooms of the new Town Hall, probably the finest municipal building in the world, for the first time in honour of the visitors, and an even more impressive view of the vast wealth and activity of the greatest continental seaport was afforded by a cruise through the harbour and a visit to the floating docks and ship-building works. The Hamburg-America Line entertained a thousand guests to lunch in the "'tween-decks" of the *Pretoria*, said to be the largest cargo steamer afloat, and this on the day before she sailed for New York with a full cargo and complement of passengers. No less hearty and no less interesting were the receptions accorded to the members of the various excursions to the Baltic shores, the Rhine and Central Germany by the local authorities and geographical societies.

The serious business of the Congress was divided into a general meeting in the forenoon from ten to one, and three simultaneous meetings in the afternoon, commencing at two o'clock, and sitting until five or even six. A time-limit for speakers was formally announced, but rarely, if ever, enforced; and the system of allowing one speaker to address the meeting as often as he liked on the same subject led to the degeneration of some of the debates into long-winded dialogues.

The programme with its additions bore the titles of no less than 150 papers, many of which were intended to be introductory to discussions. This number might have been reduced with great advantage. A few were the work of "cranks," a good many were old or of no international interest; but the great majority were new and valuable and deserving of far more complete discussion than their number made it possible for them to receive.

The departments of Geography which received most attention at the Congress were, perhaps, Antarctic Exploration, Oceano-

graphy and Plant-Geography. Dr. Erich von Drygalski gave a detailed account of the plans for the German Antarctic expedition, which is to sail in 1901, and submitted the specifications for the ship and her equipments. All the preparations for the expedition are in a forward state. Dr. Drygalski himself is the scientific leader, the captain of the ship being simply a sailing-master responsible for the navigation. Dr. Vanhöffen, who accompanied Dr. Drygalski in his Greenland expedition, goes as botanist, and several other members of the scientific staff, which will number at least six, have been chosen. Much stress is laid on the importance of co-operation with the British expedition. Dr. Drygalski hopes to land somewhere to the south of Kerguelen, that island being occupied by a land-party as a scientific base, and to advance towards the South Pole by the aid of dogs. Sir Clements Markham gave a full exposition of the plans of the British expedition. He said that the vessel for the expedition will be built of oak with an ice-casing of harder wood. She will be 172 feet long by 33 broad, with a displacement of about 1525 tons. Arrangements will be made for a magnetic observatory before the mainmast, which shall have no iron within 30 feet of it. There will be accommodation for six executive officers, including two engineers, three civilians for biology and geology, including the surgeon, and thirty-nine men. Melbourne will be the base for magnetic observations, and a party will be landed in MacMurdo Bay, near Mount Erebus, to push inland with sledges, but without dogs, the use of which involves unjustifiable cruelty. In the discussion on the Antarctic papers, Dr. Nansen strongly defended the use of dogs, the alternative being in his opinion far greater cruelty to men. Sir John Murray urged the importance of circumpolar oceanographical investigations as a preliminary to the penetration of the Antarctic ice-pack. M. Arçtowski read a paper on the oceanographical and meteorological results of the *Belgica's* voyage, and Prof. Nielsen of Christiania gave some account of Sir George Newnes' expedition under Mr. Borchgrevink.

In north polar exploration the most important papers were the first public statements regarding the scientific results of the *Fram* expedition. Dr. Nansen in a lecture of an hour and a half's duration described the North Polar Basin as revealed by his soundings, and discussed the distribution of temperature and the circulation of water in it in great detail, while Prof. Mohn in another paper gave a *résumé* of the meteorological results. It is impossible in a few lines to summarise either of these massive contributions to knowledge.

Oceanographical papers were numerous, that of Prof. Chun, the leader of the *Valdivia* expedition, exciting the greatest amount of interest. Sir John Murray discussed the distribution of deep-sea deposits over the ocean floor, and the Prince of Monaco described some of the results of his recent cruise to Spitsbergen. Several useful and really international discussions took place, culminating in the appointment of committees to draw up a systematic terminology and nomenclature for the forms of sub-oceanic relief, introduced by Profs. Wagner, Krümmel, Voiekoff and Dr. H. R. Mill, and to determine a common method of expressing the density of sea-water, introduced by Baron Wrangell and Prof. Pettersson.

There were several valuable papers on subjects involving climatology, limnology, the study of glaciers and seismology, and one on kumatology by Mr. Vaughan Cornish; indeed it would be difficult to mention any department of physical geography to which some contribution was not made.

The geography of plants was discussed with particular thoroughness, both with regard to the distribution of special types of vegetation and the more general relations of nomenclature and cartographic representation. Profs. Drude, Engler, Warburg, Krasnoff and Nehring dealt with these subjects.

The geological aspects of geography produced several papers of unusual value, including one by Prof. de Lapparent on the question of peneplains, one by Prof. Penck on the deepening of alpine valleys, and one by Mrs. Gordon (Dr. Maria Ogilvie) on the basins of southern Europe. Mr. W. Obrucheff, of St. Petersburg, gave an important account of the orography and tectonic structure of the trans-Baikal region of Siberia as revealed by the most recent observations—between 1895 and 1898; and Prof Philippson discussed the Ægean region in a similar way.

The human and historical aspects of geography were not left in the background. Prof. Ratzel discoursed on the origin and dispersal of the Indo-Germanic peoples, and Prof. Sieglin on the discovery of England in ancient times. Papers were read on the need of fresh organisation in obtaining statistics of population in unorganised countries by Dr. Scott Keltie, and on means of representing such statistics on maps by Prof. Hettner. Prof. Neovius, of Helsingfors, exhibited a remarkable atlas of Finland recently completed by the Finnish Geographical Society, in which all the conditions of the land, natural and economic, are mapped with a completeness that has never been attempted for any other country. It even includes a map showing in horse-power the available energy of the rivers.

As was to be expected there were many papers on geography in its educational aspects. Amongst these one by Prof. Ratzel on geographical position as the central fact in geographical education was perhaps the most important.

The last meeting of the Congress was to have been addressed by Prof. Hergesell on the results of international balloon investigations, but the author somewhat rashly made an ascent the previous morning in a balloon, which carried him so far towards the Russian frontier that the Congress had been formally closed before the slow means of terrestrial locomotion brought him back to Berlin.

No better bird's-eye view of the work of the Congress can be given than by presenting in a condensed form the series of resolutions passed at the final meeting, which are intended to minister to more complete international co-operation in the work of scientific investigations.

### RESOLUTIONS OF THE SEVENTH INTERNATIONAL GEOGRAPHICAL CONGRESS.

(The order is that in which the resolutions were presented.)

(1) The Congress appoints a Committee of Bio-geographers resident in or near Berlin to draw up a uniform scheme of nomenclature for plant-formations, and after consultation with non-resident specialists, to revise the same and present it to the Eighth Congress.

(2) The Congress believes that the plans for international co-operation in Antarctic exploration form an excellent basis for joint research in physical geography, geology, geodesy and biology. With regard to meteorological and magnetic work, however, they appoint an international committee to determine the general scheme and methods to be employed on the expeditions, and to endeavour to organise a system of simultaneous observations in the regions surrounding, but exterior to, the Antarctic.

(3) The Congress expresses the earnest desire that all maps, including those published in countries using English and Russian measures, should, in addition to the graphic scale, bear the proportion of lengths on the map to those in nature in the usual form $1:x$.

(4) The Congress views it as desirable that the publication of all new geographical material accompanying accounts of travel, should be supported by details regarding the methods of surveying, the instruments employed, and their verification, the calculation of astronomical positions with their probable error, and the method of utilising these data in preparing the map. Also that all maps published by scientific men, institutions or governments should be accompanied by notes of the principal fixed points.

(5) The Congress expresses the hope that a uniform system of measures will be used in all geographical researches and discussions, and recommends that the metric system of weights and measures be so employed.

(6) The Congress expresses the hope that in scientific publications the centigrade thermometer scale should, as far as possible, be employed; or, at least, the values in centigrade degrees added to those expressed on the scales of Fahrenheit or Réaumur.

(7) With regard to the proposal to introduce a decimal division of time and angles, the Congress desires to preserve the present division of time and of the circumference into 360°, but allows that the adoption of a different subdivision of the angle might be studied, and considers that in certain cases the decimal subdivision of the degree of arc presents no objection.

(8) The Congress is of opinion that the *Bibliotheca Geographica*, published by the Berlin Geographical Society, may be accepted as an efficient international bibliography of geography.

(9) The Congress considers the construction of statistical population maps to be very desirable, and appoints an international committee to draw up a scheme, at the same time expressing the hope that national committees will be formed in various countries to promote the preparation of such maps.

(10) The Congress considers the collection of data as to the

distribution of floating ice to be very important, and appeals to the hydrographic and meteorological institutes of the countries whose ships frequent high latitudes to induce the masters of vessels to keep a regular record of the occurrence of drifting ice. The Congress believes that the Danish Meteorological Institute in Copenhagen is the best adapted as an international centre for collecting the records.

(11) The Congress nominates an international committee to consider the nomenclature of the floor of the ocean, and to produce and publish at latest in time for the next Congress a chart of the ocean with revised nomenclature.

(12) The Congress hopes that the names of oceanic islands, especially in the Pacific, will be revised with a view to ascertaining and preserving the native names. Where no native names exist or can be ascertained, the names given by the discoverers should be used. The arbitrary changing of established names ought to be opposed by every means.

(13) The Congress recognises the desirability of obtaining data for a more exact estimate than now exists of countries in which there is no means of taking a census, and desires to bring the matter to the notice of such Governments as have foreign possessions.

(14) The Congress expresses sympathy with the proposal to equip an expedition in New South Wales, with the sole object of endeavouring to discover remains or traces of the route of the Leichhardt expedition, which perished in the interior of Australia fifty-two years ago.

(15) The Congress is favourable to the foundation of an international seismological society, and appoints an international committee for the study of earthquakes.

(16) The Congress believes the production of a map of the world on the scale of 1 : 1,000,000, the sheets bounded by meridians and parallels, to be both useful and desirable. The Permanent Bureau of the Congress is instructed to deal with the question, and in the first instance to secure the preparation of a projection for the map with degree-lines on the determined scale.

(17) The Congress considers the establishment of an International Cartographical Association of service, and appoints a committee to take preliminary steps.

## *THE SCIENTIFIC CONFERENCE AT WIESBADEN.*

WE refer in a leading article to one of the most important developments of scientific organisation which our time has seen. The proceedings at a recent conference at Wiesbaden, dealing with this matter, are thus stated in Monday's *Times* :—

"For several years past there has existed an Association or Cartell of the Academies of Sciences of Munich and Vienna and of the Royal Societies of Sciences of Göttingen and Leipzig, which has met yearly to discuss matters of common interest, and the combined action of these bodies has in several ways been fruitful of results. Representatives of the Royal Society of London attended the meeting held last year at Göttingen, as well as that which took place the previous year at Leipzig, chiefly with the object of discussing the project of an international catalogue of scientific literature which the society has been engaged in promoting.

"When the invitation was conveyed to the Royal Society of London to send representatives to the Göttingen meeting it was intimated that the Cartell would be glad to learn the views of the society as to the possibility of its joining the association. The delegates appointed from London were instructed to state that the Royal Society would be disposed to join provided that the organisation were so extended as to assume a truly international character. This suggestion was not only accepted in principle at Göttingen, but it was agreed that the Royal Society of London should be requested to take the steps, if thought desirable, to ascertain how far the establishment of such an international association would commend itself to the leading scientific bodies of other countries.

"The Royal Society of Sciences of Berlin, although not included in the Cartell, has for several years past been represented at its meetings. When the Royal Society of London had ascertained that the project was likely to find favour it was agreed that the Royal Society and the Berlin Academy should together issue an invitation to the Academy of Science, Paris, the Imperial Academy of Sciences, St. Petersburg, the Reale Accademia dei Lincei, Rome, the National Academy, Washington, U.S.A., as well as to the bodies included in the Cartell, requesting them to send delegates to a conference to be held in Wiesbaden on the 10th and 11th of this month.

"At the conference, excepting the Reale Accademia dei Lincei, which was unable to send delegates, although in full sympathy with the movement, all the bodies invited were represented—the Berlin Academy by Messrs. Auwers, Virchow and Diels; the Göttingen Society by Messrs. Ehlers and Leo; the Leipzig Society by Messrs. Windisch and Wislicenus; the Royal Society by Messrs. Rücker, Armstrong and Schuster; the Munich Academy by Messrs. von Zittel Dyck and von Sicherer; the Paris Academy by Messrs. Darboux and Moissan; the St. Petersburg Academy by Messrs. Famintzine and Salemann; the Washington Academy by Messrs. Newcomb, Remsen and Bowditch; and the Vienna Academy by Messrs. Mussafia, von Lang, Lieben and Gomperz.

"Prof. Auwers, one of the secretaries of the Berlin Academy, occupied the chair, and the success of the meeting was largely due to the extreme ability and tact, combined with judicious firmness, with which he conducted the proceedings. Besides showing himself a master of the three languages—German, French and English—used in the debates, he was thoroughly informed on every point which came up for discussion. Fortunately, all the delegates appeared to be actuated by the desire to co-operate, and there was little difficulty in framing statutes which all were prepared to accept.

"The immediate outcome of the conference has been that it is resolved to found an international union of the principal scientific and literary bodies of the world, the object of which will be to initiate or promote scientific enterprises of general interest recommended by one or more of the associated bodies, and to facilitate scientific intercourse between different countries. It is to be known as the International Association of Academies. A number of important bodies besides those represented at Wiesbaden are to be invited to join. General meetings of delegates from the various constituent academies are to take place, as a rule, at intervals of three years, but the interval may be varied and special meetings held if necessary. The Royal Society had proposed, prior to the conference, that the first general meeting should be held in Paris next year. At the general meetings two sections will be constituted, one dealing with mathematics and the natural sciences, the other with arts and philosophy.

"A council is to be appointed which will carry on the business in the intervals between meetings. The formation of committees of experts to initiate and promote scientific investigations of international importance is also contemplated.

"It remains to be mentioned that the Berlin Academy had also arranged for the entertainment of the delegates at the close of the debates. On the Monday evening they were invited to attend a performance of Lortzing's opera *Undine*, and on the Tuesday they were entertained at dinner in the Kurhaus. On the latter occasion Prof. Virchow occupied the chair, and opened the proceedings by toasting the delegates generally; he was followed by Prof. Darboux, of Paris, who proposed the health of the Berlin Academy. In the course of the evening, in characteristic German style, every other possible toast was proposed by one or other of the delegates.

"It is to be hoped that when the statutes framed at the conference are communicated to the various bodies interested they will meet with approval, and that the establishment of the organisation will soon be an accomplished fact. In times when political feeling is so strongly developed the provision of a common platform on which all nations can meet amicably and co-operate in furthering scientific enterprises must prove of the very greatest value; and if the spirit of amity which prevailed at the conference be extended to future meetings the success of the association is assured."

## *UNIVERSITY AND EDUCATIONAL INTELLIGENCE.*

CAMBRIDGE.—Sir Michael Foster has been reappointed a manager of the Balfour Fund for zoological research.

Mr. Yule Oldham, reader in geography, is giving three courses of lectures this term: (1) on the Geography of Europe, for history students; (2) on Physical Geography; and (3) on the History of Geographical Discovery.

The degree of M.A. honoris causa is to be conferred on Dr. Somerville, the recently-elected Professor of Agriculture.

Mr. W. N. Shaw, F.R.S., is reappointed Assistant-Director of the Cavendish Laboratory.

Prof. D. J. Cunningham, F.R.S., of Dublin, is appointed an Elector to the chair of Anatomy, and Prof. W. F. R. Weldon, F.R.S., of Oxford, an Elector to the chair of Zoology, in succession to the late Sir W. H. Flower.

Dr. D. MacAlister, of St. John's College, has been re-elected a representative of the University on the General Medical Council for five years.

Fifteen candidates have passed the recent examination in sanitary science, and have thus qualified for the Diploma in Public Health.

THE destruction of the Technical Institute at West Ham by a fire which occurred on Monday night, and was first discovered in the chemical laboratory, is a disaster to technical education in London. The Institute commenced a short time ago an admirable programme of work in science and technology, and as it was the only municipal technical institute in the metropolitan area, its career has been closely followed. The damage done is estimated at over 80,000*l.*, only part of which is covered by insurance.

THE systematic study of geography is so much neglected in this country that it is to be hoped the School of Geography recently established at Oxford will be successful. During the present term Mr. H. J. Mackinder, the University Reader in Geography, will lecture on the historical geography of the British Isles. The lecturer in physical geography (Mr. Dickson) will lecture on the climate of the British Isles. The assistant to the Reader (Dr. Herbertson) will lecture on the geomorphology of Europe; and the lecturer in ancient geography (Mr. Grundy) will lecture on the general historical topography of Greece. Dr. Herbertson will give instruction in cartography and practical geography, with field work; and during the term special attention will be given to the study of map projections, and of physical maps of all kinds.

ANOTHER addition to the laboratory equipment of our public schools has recently been made at Felsted, where new buildings for the teaching of science were opened last week. The laboratory consists of a lecture room with raised seating and a gallery, the lecture table being provided with down draught and electricity for experimental purposes, and behind it a faced wall surface for the lantern. The chemical laboratory is a room about thirty feet square to accommodate twenty-six boys, and has an adjoining balance room. In addition there is a general physical laboratory for a like number of boys, a special laboratory for senior physics, an optical room, store room and workshop. The building is in a large measure a gift of one of the governors of the school, and has been erected under the direction of Mr. A. E. Munby. It was opened by Dr. Garnett, of the London County Council, who gave an address on science as a means of general education. Sir John Gorst recently visited the building and expressed his warm approbation of the arrangements.

PRACTICAL science in rural districts, as a means of benefiting British agriculture, has, we are glad to observe, received much support lately. The meeting of the Agricultural Education Committee, held at the Society of Arts on Friday last, showed the existence of a strong feeling that active efforts should be made to secure systematic and efficient instruction, both theoretical and practical, in agricultural subjects suitable to every class engaged in agriculture; and to diffuse among the agricultural classes a more thorough appreciation of the advantages of instruction bearing directly or indirectly on their industry. The chairman, Sir William Hart Dyke, explained that the province of the committee, as a united body, was to bring pressure upon Parliament and upon public opinion to establish in rural schools rational courses of instruction bearing upon agricultural pursuits. The following resolutions were subsequently adopted:—(1) That, in the proposed organisation of the new Board of Education, due regard should be had to the interests of agricultural instruction. (2) That proper provision should at once be made at certain of the Teachers' Training Colleges for giving to those who desire it both theoretical and practical instruction in subjects bearing on agriculture and horticulture. (3) That, after a certain date to be named in next year's code, instruction in the elementary branches of natural science bearing on agriculture should be made compulsory in rural elementary schools, and that such instruction should be accompanied and illustrated by experiments, and (where possible) by practical work in plots of ground attached to the schools. (4) That county authorities be encouraged to provide experimental and school farms, and to contribute, by scholarships and otherwise, to some agricultural college or department of the first rank. The realisation of the conditions expressed in these resolutions should be desired by every one interested in national progress.

## SCIENTIFIC SERIAL.

*Wiedemann's Annalen der Physik und Chemie*, No. 9.—Dispersion of gypsum, by W. König. The author studies the dispersion of gypsum in the visible spectrum by observing the influence of wave-length upon the width of interference fringes produced by means of wedges made of that material.—Electric charge of freshly-prepared electrolytic gases, by W. Kösters. Hydrogen and oxygen are positively electrified by passing through sulphuric acid, and this may help to explain the positive charge of the same gases when produced by electrolysis. In other cases, however, the gases passed through a liquid do not assume the same electrification as when generated by electrolysis.—Further experiments with Becquerel rays, by J. Elster and H. Geitel. Thinking that the radiation of uranium and thorium compounds might be influenced by the impact of kathode rays, the authors exposed a piece of Joachimsthal pitchblende to kathode rays, but they could not trace any influence of the rays. The authors believe the Becquerel rays to be Röntgen rays of small intensity. They support this view by showing that they are not deflected by a magnet (see p. 623).—Radio-active baryta and polonium, by F. Giesel. The author describes the preparation of the radio-active barium salts. He has not yet succeeded in isolating the active principle, whether radium or polonium.—Canal and kathode rays, by P. Ewers. The writer does not share the prevalent opinion that canal rays consist of projected anode particles, since the quantity of electricity conveyed by them varies with the material of the kathode, but not with that of the anodes. He concludes that the canal rays consist of positive ions of the material of the kathode, but the matter thus conveyed to the wall is so small that it would require 288 hours of continuous working to deposit one milligramme of aluminium.—Law of development of Hittorf's dark space, by H. Ebert. Hittorf's dark space is the narrow space which immediately adjoins the luminous kathode layer. Its width increases as exhaustion proceeds, and does so in accordance with a geometrical series when the pressure diminishes in another geometrical series. The indices of the series are, however, generally different.—Magnetic susceptibilities of inorganic compounds, by S. Meyer. Judging from their compounds, the rare elements lanthanum, cerium, praseodymium, samarium, gadolinium, and especially erbium, must be strongly magnetic. Erbium oxide is four times as strongly magnetic as $Fe_2O_3$, and if the conclusion as to their bases is correct, erbium must be, weight for weight, six times as strongly magnetic as iron. This would have an important practical signification if erbium were to be found in large quantities.

## SOCIETIES AND ACADEMIES.

### PARIS.

**Academy of Sciences**, October 16.—M. van Tieghem in the chair.—On the positions of equilibrium of a ship carrying liquid cargo, by M. Appell. The author develops a problem of M. Guyou, giving a means of finding the positions of equilibrium and discussing their stability.—Method of setting a collimator, by M. G. Lippmann. The slit is observed with an auxiliary telescope, and between this and the collimator a biplate is inserted. In general two images of the slit are observed, but on adjusting the collimating lens, at one point the two images coincide; the rays issuing from the collimator are now parallel. The accuracy of the adjustment is limited only by the resolving power of the telescope.—Production of ozone by the decomposition of water with fluorine, by M. Henri Moissan. A rapid current of fluorine, prepared in a copper apparatus, is passed

into water kept at 0°. The ozonised oxygen thus set free was carefully analysed by treatment with potassium iodide and measuring the iodine set free. The percentage of ozone was on one occasion as high as 14·4 per cent., and this preparation, although somewhat delicate, is not costly. The ozone produced in this way is absolutely free from all trace of oxides of nitrogen, and may possibly have industrial applications.—The preventive qualities of the blood serum of an immunised heifer against contagious peripneumonia in cattle, by MM. S. Arloing and Duprez. The direct inoculation for peripneumonia suggested by M. Willems has two disadvantages: some time is required to develop the protective effects, and occasionally fatal tumours occur. A heifer was directly inoculated with gradually increasing amounts of venom until it became capable of resisting a dose five hundred times greater than would be sufficient to kill an unprotected animal. The serum of this heifer was used in the experiments, which were not altogether conclusive, since one of the injected animals caught the disease, whilst another, although unprotected, escaped.—Report on an earthquake at Smyrna on September 20, by the French Consul General at Smyrna.—Observations of the Giacobini Comet (September 29, 1899), made at the Observatory of Algiers, with the equatorial of 31·6 cm. aperture, by MM. Rambaud and Sy.—On a problem relating to the congruences of right lines, by M. E. Goursat.—On the classification of projective groups in space of $n$ dimensions, by M. F. Marotte.—Theory of the number of roots of an algebraic equation comprised in the interior of a given circumference, by M. Michael Petrovitch.—On the reactions of induction of alternators, by M. A. Blondel.—Experiments in telegraphy without wires, carried out between Chamonix and the summit of Mont Blanc, by MM. Jean and Louis Lecarme. The communications were interfered with by the ice, or by the absence of water in the soil; neither were the effects of atmospheric electricity sufficient to stop the messages, but during the time the electric light at Chamonix was in action working was impossible.—Radiographic bulb with a cold antikathode, by MM. Abel Bugnet and Victor Chabaud. The platinum tube forming the antikathode is fused directly to the glass, and is kept cool by cold water. Very powerful discharges from large induction coils can be used with this tube without any heating of the platinum resulting.—On a new radio-active material, by M. A. Debierne. A new radio-active substance has been isolated from pitchblende. It is distinguished from polonium and radium by its chemical properties, which resemble titanium very closely, and also by the fact that it is not spontaneously luminous. The rays emitted by this substance, for which no name is as yet suggested, are about 100,000 times stronger than those given off by uranium. They render gases capable of discharging electrified bodies, excite the phosphorescence of barium platinocyanide, and affect photographic plates.—On the atomic weight of boron, by M. Henri Gautier. The author, after reviewing the earlier work of Berzelius, Abrahall, and Ramsay and Aston, attempts to prepare compounds of boron of the constancy of composition of which there can be no doubt, and selects the sulphide $B_2S_3$ and carbide $B_6C$ for a preliminary study.—On anhydrous magnesium carbonate, by M. R. Engel.—On the heat of oxidisation of tungsten, by MM. Delépine and Hallopeau. The usual methods of combustion at ordinary pressure, combination with a halogen, attack by water or acid having failed for tungsten, the method of burning in the calorimetric bomb was tried, and after some preliminary experiments was found to give good results, the mean value per gram of tungsten being 1062 calories. In forming the oxides $TuO_2$ and $TuO_3$, each atom of oxygen has nearly the same calorific value.—Action of potassium-ammonium upon arsenic, by M. C. Hugot. With the alkaline ammonium in excess, $AsK_3$ is formed; with arsenic in excess, $As_4K_2$.—Action of bromine in presence of aluminium chloride upon some chloro-benzenes, by M.M. A. Mouneyrat and Ch. Pouret. Bromine acts readily upon chlorobenzene in presence of aluminium chloride, and gives an excellent yield of $p$-bromo-chlorbenzene. The following compounds have been obtained by this method: $C_6Br_5Cl$, [1, 4] $C_6Br_4Cl_2$, [1, 2, 4] $C_6Br_3Cl_3$, [1, 2, 4, 5] $C_6Br_2Cl_4$, and $C_6Br_4Cl(CH_3)$.—On the constitution of the colouring matter of leaves; chloroglobin, by M. Tsvett.—Demonstration of the disaggregation of leucocytes and the solution of their contents in the blood plasma during hypoleucocytosis. Influence of intravascular leucolysis on the coagulation of the blood, by M. Henri Stassano.—Germination of the seed of the carob; production of mannose by a soluble ferment, by MM. Ed. Bourquelot and H. Hérissey. During the germination of the carob seed there is soluble ferment produced, which acts upon the stored albumen similarly to diastase upon amylaceous albumens, mannose and galactose being the products.—On *Aplosporidium*, a new order of the class of Sporozoa, by MM. Maurice Caullery and Félix Mesnil.—Calcified suberous layers from the coal measures of Hardinghen, by M. C. Eg. Bertrand.—On the composition and food value of the principal fruits, by M. Balland.—Submarine lithology of the coasts of France, by M. J. Thoulet.

## DIARY OF SOCIETIES.

*THURSDAY*, October 26.

Camera Club, at 8.15.—Illusions and Anomalies of Vision: Shelford Bidwell, F R.S.

*FRIDAY*, October 27

Physical Society, at 5.—The Magnetic Properties of the Alloys of Iron and Aluminium: Dr. S. W Richardson.—Exhibition of a Model illustrating a Number of the Actions in the Flow of an Electric Current: G. L. Addenbrooke —Repetition of some Experiments with the Wehnelt Interrupter devised by Prof Lecher: W. Watson

Institution of Mechanical Engineers, at 7.30.—The Incrustation of Pipes at Torquay Water Works: William Ingham.—A Continuous Mean-Pressure Indicator for Steam Engines: Prof. William Ripper.

*WEDNESDAY*, November 1.

Entomological Society, at 8—Exhibition of Lepidoptera from Bulgaria: H. J. Elwes, F.R.S, and Mrs. Nicholl.

Society of Public Analysts, at 8.—The Meaning of the Acetyl Value in Fat Analysis (with Lantern Illustrations): Dr. J. Lewkowitsch.

*THURSDAY*, November 2.

Linnean Society, at 8.—On the Proliferous State of the Awn of Nepal Barley: Rev. Prof. Henslow.—On the Hyobranchial Skeleton and Larynx of the New Aglossal Toad, *Hymenochirus Boettgeri*: Dr. W. G. Ridewood.—On the Eye-spot and Cilium in *Euglena viridis*: Harold Wager.

Chemical Society, at 8.—The Theory of Saponification: J. Lewkowitsch.—The Action of Dilute Nitric Acid on Oleic and Elaidic Acids: F. G. Edmed.—Tetrazoline: Siegfried Ruhemann and H. E. Stapleton.—On Ethylic Dibromobutanetetracarboxylate and the Synthesis of Tetrahydrofurfuran-αα′-dicarboxylic Acid: Dr. Bevan Lean.—(1) Camphoroxime. Part III. Behaviour of Camphoroxime towards Potassium Hypobromite; (2) Optical Influence of an Unsaturated Linkage on certain Derivatives of Bornylamine: Dr. M. O. Forster.

## ROYAL INSTITUTION OF GREAT BRITAIN,

ALBEMARLE STREET, PICCADILLY, W.

Prof. L. C. MIALL, F.R.S., will on Thursday next, May 25th, at Three o'clock, begin a Course of Two Lectures on "Water Weeds."

Subscription for this Course, Half-a-Guinea.

## INDIAN GEOLOGICAL SURVEY.

Required for the Geological Survey of India, a Specialist, who should have a thorough training in Field Geology, and experience in carrying out Geological Surveys, as well as in conducting economic inquiries in connection with Coal-fields.

Candidates, under 40 years of age, are invited to apply to the Under-Secretary of State, India Office, Whitehall, London, not later than the 15th June, with Certificates of Qualifications and of Age.

The Salary of the Post is 900 Rupees a month; and the Appointment will be for a term of five years.

Further particulars will be furnished on written application to the REVENUE SECRETARY, India Office, Whitehall.

A. GODLEY, Under-Secretary of State.

India Office, 3rd May, 1899.

## SWANSEA MUNICIPAL TECHNICAL SCHOOL.

G. S. TURPIN, M.A., D.Sc., Principal.

Applications are invited for the Post of ASSISTANT LECTURER in MECHANICAL ENGINEERING.

Candidates must have had Workshop experience and a Scientific training; proved ability to teach would be a strong recommendation

The Salary offered is £120 per annum. A Statement of Duties may be obtained on application from the SECRETARY OF THE SCHOOL.

Applications, with one set of copies of testimonials, should be received not later than Wednesday, May 24th.

L. COLLWYN LEWIS, Secretary.

## BOROUGH OF SWANSEA.

INTERMEDIATE AND TECHNICAL SCHOOL FOR BOYS.

An ASSISTANT MASTER will be required in September to teach PHYSICS (THEORETICAL and PRACTICAL) and some MATHEMATICS.

Candidates must have had experience in teaching, and be well acquainted with Laboratory Work in Physics, as taught in Schools.

The Salary offered is £150 per annum. Further particulars may be obtained on application from the SECRETARY.

Applications, with one set of copies of testimonials, should be addressed to the HEAD MASTER, and should reach him not later than Wednesday, May 24th.

L. COLLWYN LEWIS, Secretary.

## UNIVERSITY COLLEGE, LONDON.

JODRELL PROFESSORSHIP OF ZOOLOGY.

This Chair will be vacant by the resignation of Prof. Weldon at the close of the present Session.

Applications, accompanied by such testimonials as Candidates may wish to submit, should reach the Secretary by Monday, June 5, 1899.

Further information will be sent on application to the SECRETARY.

The new Professor will enter on his duties in the October following.

J. M. HORSBURGH, M.A., Secretary.

## UNIVERSITY OF ST. ANDREWS.

CHAIR OF PATHOLOGY.

In accordance with the terms of Ordinance No. 47 (St. Andrews, No. 6) of the Commissioners, under the Universities (Scotland) Act 1889, the University Court will appoint a PROFESSOR OF PATHOLOGY, who shall conduct Classes at Dundee qualifying for graduation in Medicine; the appointment to date from October 1, 1899. Applications, accompanied by twenty copies of testimonials, to be lodged by 21st JUNE next, with Mr. J. E. WILLIAMS, Secretary of the University, from whom further information may be obtained.

St. Andrews, May 1899.

## UNIVERSITY OF ST. ANDREWS.

The UNIVERSITY COURT OF ST. ANDREWS will, at a meeting to be held in the month of July, appoint an ADDITIONAL EXAMINER for Graduation in the subject of NATURAL HISTORY.

Applications, with testimonials, to be lodged by 21st June next with the undersigned, from whom further information may be obtained.

JNO. E. WILLIAMS, Secretary.

St. Andrews, May, 1899.

## RESEARCH.

**CHEMISTRY. PHYSICS. BACTERIOLOGY.**

Well-fitted LABORATORIES can be used for RESEARCH at any hour convenient to Workers. Dark Room for PHOTOGRAPHIC and other Work. $\frac{1}{12}$ immersion for MICRO-PHOTOGRAPHY. Workshop for making Apparatus. ELECTRIC MAINS, powerful Constant Currents.—"T." 9 Heathcote Street, Gray's Inn Road.

# BIRKBECK INSTITUTION,

Breams Buildings, Chancery Lane, E.C.

PRINCIPAL: G. ARMITAGE-SMITH, M.A.

## DAY AND EVENING CLASSES.

**UNIVERSITY OF LONDON.**—Complete Day Courses for all the Examinations in Science, and Complete Evening Courses for all the Examinations for the Science, Arts, and Law Degrees.

**SCIENCE CLASSES** in every Branch, with Practical Work. Well-equipped Laboratories for Chemistry, Physics, Biology, Botany, Geology, Mineralogy, and Metallurgy.

**CONJOINT BOARD:** Lectures and Practical Work in Chemistry, Physics, Biology, and Practical Pharmacy. NEW TERM for Conjoint Board and Inter. M.B. Examinations has just commenced.

*Prospectus, Calendar (6d.), and Syllabuses of Classes on application to the Secretary.*

## EGYPTIAN GOVERNMENT SCHOOLS.

FIVE ASSISTANT MASTERS REQUIRED, to begin work in October, in Cairo Secondary School, under Ministry of Public Instruction. Masters to teach in English exclusively—one of them principally Physics and Chemistry, two of them principally Mathematics, and the two others principally English. Over three hundred boys. English Head Master. Teaching hours on an average, three daily—Fridays excepted. Summer vacation not less than two months annually. Graduates of Oxford or Cambridge preferred. Salary about £295 per annum (L. Eg. 288), rising to about £393. Civil Service Pension Scheme.

Allowance for passage out to Egypt.

Applications, accompanied by copies only of testimonials, must be sent in before June 30, 1899, marked outside "English Masterships," and addressed to the SECRETARY-GENERAL, Ministry of Public Instruction, Cairo, Egypt, to whom Candidates may apply for further information.

## MUNICIPAL TECHNICAL SCHOOLS, PLYMOUTH.

WANTED, an ASSISTANT MASTER (Undergraduate in Science preferred), mainly for School of Science work. Must have good teaching experience. Salary £100 per annum, rising by annual increments of £10 to £120. Full particulars from

T. W. BYFIELD, Secretary.

**RESEARCH (Biological). — COLLABORATEUR (or PUPIL) WANTED** by Man of Science in important work to be shortly published. Use Laboratory. Terms by arrangement. Good Mathematics and Physics preferred.—Write "SCIENCE," c/o NATURE.

**TUITION.—ALL EXAMINATIONS —MEDICAL AND SCIENTIFIC.** Well-fitted Laboratories.—"R C.," 9 Heathcote Street, Mecklenburgh Square.

**PALÆARCTIC MOLLUSCA.**—One of the largest Collections in Europe, containing many Types, together with an extensive Malacological Library, for Sale.—For particulars and price apply to "G. W.," c/o of GOULD'S Advertising Offices, 54 New Oxford Street.

## Sale by Auction.

TUESDAY, MAY 30.

A VALUABLE COLLECTION OF BRITISH AND FOREIGN BIRDS AND EGGS.

**MR. J. C. STEVENS will Sell the above** by Auction, at his Great Rooms, 38 King Street, Covent Garden, as above, at 12.30.

On view the Day prior, 10–4, and Morning of Sale, and Catalogues had.

Apparatus for estimation of sulphur in spent oxide.

# FREDK. JACKSON & Co.

(Late MOTTERSHEAD & CO.),

## 14 CROSS STREET, MANCHESTER.

*Goods Entrance: 10 Half-Moon Street,*

## LABORATORY FURNISHERS,

Importers, Manufacturers, and Dealers in

**CHEMICAL AND PHYSICAL APPARATUS**

Of every Description.

**Fine Chemicals, Volumetric Solutions, Plain and Stoppered Bottles,**

AND EVERY LABORATORY REQUIREMENT.

Illustrated Catalogue of Apparatus, with Price of Chemicals, free on application.

Telegraphic Address—"APPARATUS, MANCHESTER."

Telephone Number—2038.

## MASON UNIVERSITY COLLEGE, BIRMINGHAM.

DIPLOMA COURSES IN CIVIL, MECHANICAL, AND ELECTRICAL ENGINEERING.

Professor F. W. BURSTALL, M.A. (Camb.), A.M.I.C.E.
Lecturer on Technical Electricity—D. K. MORRIS, Ph.D., A.I.E.E.
Assistant Lecturer and Demonstrator—F. H. HUMMEL, A.M.I.C.E.

The Technical Engineering Classes include :—

LECTURES on the Strength of Materials, Theory of Steam, Gas, and other Heat Engines, Hydraulics, Machine Design, Strength of Structures, Distribution of Power

DRAWING.—Design of Tools, Prime Motors, Dynamos, and other forms of Machinery.

FIELD WORK.—Practical Surveying in the Field throughout the Summer Term.

ENGINEERING LABORATORY.—Determinations of the Strength of Materials, including Compressive, Bending, Tensile, and Torsion Tests; Experimental Study of the Steam Engine and Boiler, Frictional Efficiency Tests, the Flow of Water over Weirs and through Orifices, &c.

LECTURES and DEMONSTRATIONS on all branches of Electrical Engineering.

ELECTRICAL LABORATORY.—Testing of Continuous and Alternate Current Machinery, Electrical Instruments, Meters, Lamps, and Batteries, Insulation and Magnetic Testing Work.

The Courses also include :—

Mathematics—Principal R. S. Heath, M.A., D.Sc.
Physics—Professor J. H. Poynting, D.Sc., F.R.S.
Chemistry—Professor P. F. Frankland, B.Sc., Ph.D., F.R.S.
Geology—Professor C. Lapworth, LL.D., F.R.S., F.G.S.
Metallurgy—Lecturer, G. Melland, B.Sc., A.R.S.M.

The DIPLOMA, which carries with it the Associateship of the College, may be obtained at the end of *three* years' study.

The SESSION 1899–1900 commences on Tuesday, October 3. Professor BURSTALL will attend to consult with intending Students on October 2, from 10 a.m. to 1 p.m.

For DETAILED SYLLABUS, with Particulars of Fees, Scholarships, &c., apply to the Secretary.

## QUEEN'S COLLEGE, GALWAY.

The Matriculation Examination of Session 1899–1900 commences on October 20. Matriculation Certificates of any University within the United Kingdom are accepted.

All Lectures, Scholarships, Exhibitions, and Prizes are open to Students of either sex.

The Scholarship Examinations in Arts, Medicine, and Engineering commence on October 19.

DEPARTMENTS OF
SCIENCE, MEDICINE, AND ENGINEERING.

| | |
|---|---|
| MATHEMATICS ... | Prof. Alfred C. Dixon, M.A., Sc.D., F.R.U.I., late Fellow of Trinity College, Cambridge. |

| MATERIA MEDICA .. | Prof. Nicholas W. Colohan, M.D., M.Ch. |
| GYNÆCOLOGY ... ... | Prof Richard J. Kinkead, B.A., M.D., L.R.C.S.I. |

Prospectus of the Courses and Regulations for Scholarships, &c., can be had on application to the

REGISTRAR,
Queen's College, Galway.

## UNIVERSITY OF GLASGOW.

COURSES IN ENGINEERING SCIENCE.

The Session opens on October 19.
Engineering—Prof. ARCHIBALD BARR, D.Sc., M.Inst.C.E.
Naval Architecture and Marine Engineering—Prof. J. HARVARD BILES, M.I.N.A.
Electrical Engineering—Mr. JOHN D. CORMACK, B.Sc., M.I.E.E.
Chemistry—Prof. JOHN FERGUSON, M.A., LL.D.
Natural Philosophy—(New Professor to be appointed before opening of Session.)
Mathematics—Prof. WILLIAM JACK, LL.D.
Geology—Prof. JOHN YOUNG, M.D.

Prospectuses of the Courses, with regulations for the Degrees of B.Sc. and D.Sc. in Engineering Science, and a List of Bursaries and Scholarshi open to Science Students, can be had from the Assistant Clerk.

# BIRKBECK INSTITUTION,

Breams Buildings, Chancery Lane, E.C.

## Science Classes with Practical Work.

**Day and Evening Classes** for University of London B.Sc.; Prelim. Scientific, Inter. M.B. Examination and for Conjoint Board, Dental and Pharmaceutical Examinations.

**Evening Classes** in all stages for Science and Art Department Examinations.

**Highly-equipped Laboratories.**
Chemistry, Physics, Biology (Zoology and Botany), Metallurgy, Geology and Mineralogy, Microscopy.

**Prospectus free. Calendar 6d., Post 8d., on application to Secretary.**

## UNIVERSITY OF ST. ANDREWS.

COURSES IN ENGINEERING AT UNIVERSITY COLLEGE, DUNDEE.

The Winter Session will commence on October 11. Applicants for Bursaries and Scholarships should give in their names by September 23.

ENGINEERING.
Prof. T. CLAXTON FIDLER, M. Inst. C.E.
Assistant Lecturer in Drawing: Mr. W. A. Thain, M.I.M.E.

PHYSICS.
Prof. J. P. KUENEN, Ph.D.
Assistant Lecturer and Demonstrator: Mr. J. M'Cowan, M.A., D.Sc.
(Electrical Engineering is taken in this Department.)

MATHEMATICS.
Prof. J. E. A. STEGGAL, M.A., Cambridge.

CHEMISTRY.
Prof. JAMES WALKER, D.Sc., Ph.D.

The Calendar, which can be obtained on application, contains the regulations for the degrees of B.Sc. and D.Sc in Engineering, and a list of the Bursaries, which are open to Students of the 1st, 2nd, and 3rd year, as well as a Prospectus of the Courses and Laboratory Work.

R. N. KERR, Secretary.

University College, Dundee, September 5, 1899.

## UNIVERSITY COLLEGE, LIVERPOOL.

(VICTORIA UNIVERSITY.)

DEPARTMENT OF ENGINEERING.

Session 1899-1900 commences October 2. Complete Courses of Instruction are arranged in

(1) Civil Engineering,
(2) Mechanical Engineering,
(3) Electrical Engineering.

These Courses enable Students to qualify for University Degrees, and for the College Certificates in Engineering. They comprise, in addition to special Engineering Lectures and Laboratory Work, Instruction in Mathematics, Physics, Electrotechnics, and Chemistry.

| | |
|---|---|
| Harrison Professor of Engineering | H. S. Hele-Shaw, LL.D., F.R.S., M.Inst.C.E. |
| Lyon Jones Professor of Experimental Physics ... ... ... | Oliver J. Lodge, D.Sc., F.R.S., M.Inst.E.E. |
| Professor of Mathematics ... ... | F. S. Carey, M.A., late Fellow of Trinity College, Cambridge. |
| Grant Chair of Chemistry ... ... | J. Campbell Brown, D.Sc., F.I.C. |

The special Engineering Prospectus can be obtained on application to the Registrar.

## UNIVERSITY COLLEGE, LIVERPOOL (VICTORIA UNIVERSITY).

SCIENTIFIC DEPARTMENTS.

SESSION 1899-1900 will open on MONDAY, OCTOBER 2.

| | |
|---|---|
| PHYSICS ... ... ... .. | Prof. Oliver Lodge, D.Sc, F.R.S. |
| CHEMISTRY ... ... | Prof. J Campbell Brown, D.Sc. |
| ZOOLOGY ... ... ... | Prof. W. A. Herdman, D.Sc., F.R.S. |
| BOTANY ... ... ... ... | Prof. R. J. Harvey Gibson, M.A., F.L.S. |
| PHYSIOLOGY .. ... | Prof. C. S. Sherrington, M.A., M.D., F.R.S |

In addition to Courses preparing for Victoria and London University Degrees, the Laboratories in the above Departments are open to Male and Female Students alike for Study and Research at scales of Fees which can be obtained on application.

For full information as to Courses in the Science, Arts, and Medical Departments, apply to the Registrar,

E. LONDINI, D.C.L.
